The nature of these diseases is not well understood. They are not due to a micro-organism, bacteria, or a special bacillus, so far as known; in spite of numerous researches we are still in the dark as regards their origin.

The history of the treatment of dysentery shows the diverse and discordant opinions entertained by authors regarding the use of ipecacuanha. No one remedy can be considered a specific for either of the diseases in question. The writer, having been a great sufferer from both, briefly related his experience and experiments upon himself with various remedies.

He is convinced that fuming nitrous acid, 43°, as furnished by Powers & Weightman, of Philadelphia, is the best remedy that we have; it may be reinforced by opium, if necessary. His favorite formula is the following:

℞. Acidi nitrosi, 43° ..... f ʒ j.
Tinct. opii ..... f ʒ ij.
Aquæ destil ..... f ʒ vj.
Syr. simpl ..... ad f ʒ viij.
M. Sig.—A tablespoonful in one wineglassful of water every three hours.

This remedy will afford relief in the majority of cases of dysentery and camp diarrhœa. Oil of turpentine is most valuable in the latter disease, especially in the hemorrhagic form as well as in the chronic diarrhœa met with in private practice. The writer has for years used with success the following formula, which possesses the advantage of being pleasant to the taste, and is readily taken by children:

℞. Acaciæ pulv ..... ʒ jss.
Ol. terebinth ..... f ʒ ij. ʒ ij.

Misce et adde:

Aquæ ..... f ʒ iij.
Syr. simpl ..... ad f ʒ xij.
M. Sig.—One teaspoonful every three hours to adults.

It will be noticed that this emulsion contains twenty drops to the drachm, a quantity which is less likely to cause strangury than a smaller dose. It may be reinforced by tr. opii, to prevent undue catharsis. The dose for children should, of course, be proportionate to their age. I have found this combination invaluable.

In camp diarrhœa, another efficient combination is the following, which will be found useful also in summer diarrhœa:

℞. Hydrarg. chlor. mit. ..... gr. ij.
Pulv. ipecac ..... gr. iij.
Opii ..... gr. v.
M. et in chartulas no. x. divide.
Sig.—One every three hours.

The next paper was read by Dr. Joseph R. Smith, U.S.A., of New York, upon

THE BEST FORM OF REPORT OF SICK AND WOUNDED OF ARMIES.

The object of such a report was described, and the form adopted by various European armies shown. Of these, that of the Prussian army is, in the opinion of the writer, the best. A model of a form suitable for all armies, designed by the author, was presented.

Five propositions were formulated for adoption by the Section, the first stating the objects of report of medicine and surgery; the second the frequency and periodicity of the same; the third recommending simplicity and uniformity; the fourth expressing preference for the Prussian system of classification; the fifth urging the adoption of the model form here presented, and directs the Secretary of the Section to communicate their opinion to the medical bureau of all nations represented in the Congress.

An essay by Dr. Chas. W. Brown, of Elmira, N. Y., upon

THE ETIOLOGY AND TREATMENT OF TETANUS

was read. The author began by saying that the cause of the disease is still enshrouded in doubt, but was more probably due to ascending neuritis than to the irritation of peripheral nerves. He considers the disease a specific, contagious, and infectious one, which, according to Rosenbach, is caused by a bacillus, his experiments having shown that rabbits and mice inoculated with material from a case of tetanus died of the disease. The author adverted to some experiments made by various observers upon the horse, and proceeded to compare a true case of the disease with one of cerebro-spinal meningitis, which, he thought, had often been mistaken for idiopathic tetanus; in fact, his experience and observation had cast a doubt in his mind as to the existence of such a disease as idiopathic tetanus, which was always the result of some wound, however slight. After an interesting account of a case met with in his practice he approached the subject of treatment, which he characterized, as a rule, as very unsatisfactory. The wound should be, if necessary, freely opened and cleansed with some antiseptic fluid, and dressed in accordance with the methods of modern asepsis. Isolation and rest in a dark room, free from air-currents, were of great importance. The removal of wounded parts has not given good results in traumatic tetanus. Supporting measures are indicated in the disease, and the intelligent use of stimulants. The use of concentrated foods was not to be overlooked.

Quinine had been in some cases apparently used to advantage, in enormous doses, some giving as much as two hundred and sixty grains in one dose. He had himself administered it in doses of one hundred grains every hour for some time; this case recovered, and no bad results followed from the injection of such a large quantity of the drug. Fowler's solution, cannabis indica, morphia, cocaine, the bromides, had in turn been tried in vain, although the latter, particularly bromide of potassium, had been strongly recommended by Dr. McCord, of Kentucky, in twenty-grain doses, every hour. The use of pounded ice and the ether spray along the spine should always be resorted to.

The President, Dr. Smith, announced that the paper which had been promised upon

THE MICROBIC ORIGIN OF TETANUS,

by Dr. William Browning, of Brooklyn, N. Y., had not been received. He then called upon Dr. J. McF. Gas-

ton, of Atlanta, Ga., to open the discussion upon this interesting subject.

Dr. Gaston, at the outset, regretted exceedingly that the paper just mentioned had not been presented, as he had expected from it, and, as a result of the author's experiments, the presentation of new data of a definite nature upon this subject. In the absence of any such data, and relying upon his own experience with the disease, the speaker's views were not in harmony with those of Dr. Browning, concerning its bacterial origin, contagious or infectious nature. Dr. N. Senn, of Chicago, in a recent lecture, appeared to take for granted the bacterial origin of tetanus, the author of the paper under discussion appeared to hold the same views, but has not eliminated the doubt which may exist in regard to this etiological factor. It is begging the question to claim that tetanus is due to a bacillus, because a certain bacillus of a distinctive character has been found in the course of the disease, since such an organism may be a mere accompaniment or result, and have no causative influence whatever. Regarding the claim of contagiousness or infectiousness, chiefly based upon the synchronous or subsequent appearance of the disease in man or animals in the same locality, it should be considered that there may be certain predisposing atmospheric conditions in such locality which may account for the occurrence of the disease without implying its infectious or contagious nature in the ordinary acceptation of the terms.

In the speaker's experience, suppurating wounds do not often cause tetanus. The disease may be due to the development of some ptomaïne, but the question of its origin is still *sub judice*.

As for the treatment, the use of chloroform and the thorough saturation of the system with chloral and potassium bromide offer the best chance of success. The speaker had observed eighteen cases of traumatic tetanus, treated in this manner, of which ten cases had recovered.

Afternoon Session.

The first paper of the session was read by Dr. J. W. S. Gouley, of New York, on

the practical consideration of human nosography.

The author first considered the importance of a correct and thorough nomenclature of diseases, and the causes that had retarded the progress of this science. To be of practical utility, nosography should be established upon a sound basis. The defects in the past and present nomenclature of diseases were chiefly enumerated, and suggestions given for their remedy. The paper concluded with the presentation of propositions looking toward an improved classification of diseases.

Dr. Simeon Tucker Clarke, of Lockport, N. Y., spoke of the importance of this subject and agreed, in the main, with the views of the author.

Dr. Harrison, of Washington, Dr. Didama, and Dr. Frederick Hyde, of Syracuse, N. Y., discussed the subject and presented their views relative to its importance.

Dr. Hingston, of Montreal, Canada, spoke of the necessity of such a revision as that proposed, and Dr. Bontecou, of Troy, N. Y., referred to the simplicity of the Prussian nomenclature of diseases, as compared with ours.

Dr. Gouley concluded the discussion by suggesting that co-operative movement was needed to reach the desired end of a perfect nomenclature.

The second paper, entitled

what class of gun-shot wounds and injuries justify resection or excision in modern warfare?

was read by the author, Dr. Reed Brockway Bontecou, of Troy, N. Y.

After a clear definition of the terms, the author entered upon a consideration of the value of operations as compared with the results of expectant treatment or amputation, referred to the advantages of excisions and their reduced mortality under the antiseptic method, and gave statistics of gun-shot wounds of cranium, clavicle, scapula, and shoulder-joint. The fractures of the hip-joint were next considered. The results of resections of lower extremities were not satisfactory, with regard to their future usefulness. The condition demanding excision of the shaft of the femur in gun-shot fractures were chiefly enumerated. In conclusion the author adverted to the favorable statistics of antiseptic treatment without operation, and to the encouraging results of resection of the knee-joint under the same method of treatment.

Dr. Goodman, of Philadelphia, after a few remarks upon the paper, reported some cases of resection of the femur after the battle of Chancellorsville, attended with fatal result.

Dr. Henry Janes, of Waterbury, Vt., read an important paper, giving the results of his experience during the late war, with

gun-shot fractures of the femur.

The author's conclusions upon this interesting subject are based upon the results of no less than 427 cases occurring in his service, and treated by himself, or under his immediate observation, in two field hospitals in his charge during the year 1862 and 1863.

Of these fractures 95 were in the upper third of the bone, all of which were treated conservatively, giving a mortality of forty-six per cent. at last reports; 125 were in the middle third, 102 of these being treated conservatively, with a mortality of thirty-two per cent., 23 were amputated, mortality forty per cent.; 207 cases were in the lower third of the bone; 67 of these, not including knee-wounds, were treated by the conservative method, with a mortality of twenty per cent.; 140 cases were amputated, resulting in a mortality of thirty-five per cent. Besides these 427 cases, there were 34 fractures involving the knee-joint, treated conservatively, with a mortality of eighty-five per cent. The cases requiring amputation terminated earliest, but about one-eighth of them suffered from painful and tedious osteitis. Up to about forty years of age, advance in life did not seem to increase the rate of mortality. The author's conclusions are the following:

Antero-posterior wounds did no better, in his experience than the transverse. Fractures caused by bullets moving with great velocity were fraught with more danger than those moving at a lower rate of speed.

Wounds occurring in prisoners did not do so well as those in their captors under the same conditions; this was probably due to the incident moral influences.

Gun-shot fractures sometimes united as readily as simple fractures.

False joint occurred but once among the two hundred and sixty-three cases treated conservatively.

Secondary hemorrhage occurred only in nine cases, in several times it was incident to septic poisoning.

Tetanus only occurred once.

Hospital gangrene seemed to be induced in the autumn of 1863 by bad ventilation and the occurrence of cold, damp weather.

The shortening, in the cases which completely recovered was generally of more than one inch; it was, in several instances, increased by the too early use of the limb.

The formation of callus was sometimes so irregular and excessive in amount as to impede muscular action; it sometimes encroached upon an artery or nerve and caused secondary hemorrhage or neuralgia. In some cases the callus was absorbed in the course of septic inflammation.

Refractures, caused by falls and similar accidents, generally reunited readily when the wounds in the soft parts were healed.

The limbs often became much more useful than any

artificial substitute; the author has unfortunately no statistics bearing upon this subject to offer.

Regarding the treatment of injuries of this nature, he would enjoin the surgeon *not* to saw off the ends of fractured bones, and not to use too much force in tearing off fragments of bone still attached to the periosteum. Moderate, simple extension by weights and pulleys is the best in the majority of cases; in some of the cases that did the best no extension was used. He would advise the dry dressing of wounds, with plenty of absorbents, rather than with water-dressings. Strict antisepsis, according to the modern idea, is impossible in large hospitals on the battle-field.

In conclusion, the author spoke of the necessity of a liberal diet, the intelligent use of stimulants, and due regard to the sanitary precautions in the camp or hospital in which this class of injuries are treated.

Dr. Robert Reyburn, of Washington, desired to know what proportion of the doctor's cases had been reated in tents and in buildings.

Dr. Janes said the majority of the cases were treated under canvas, with free access of air; with the advent of the cold and damp weather of winter, the ventilation was not so perfect, as it was difficult to impress upon the soldiers the importance of free ventilation, at a time when they were suffering from the cold. It was, as previously stated, at this time that hospital gangrene set in.

Dr. Reyburn, in my experience, the kind of hospital in which the wounds under consideration are treated has much to do with the mortality; the treatment in tents I consider the best; unfortunately, most of the cases observed by him in the service could not be treated under such favorable conditions, and he had to report a mortality of about seventy-five per cent. The results achieved by Dr. Janes were most remarkable, and show what can be done by conservative surgery.

SECTION IN OBSTETRICS.

Thursday, September 8th—Fourth Day—Morning Session.

Dr. Alexander Simpson, of Edinburgh, Scotland, occupied the chair—Dr. Miller being called away by a death in his family. The Section passed resolutions of condolence and sympathy.

Dr. Emil Poussie, of Paris, France, read some remarks on a case of

TYPHOID FEVER IN THE PUERPERAL WOMAN.

Seven days after labor, grave symptoms of true typhoid fever appeared, the disease running its course and the patient recovering. The report was made to call attention to the importance of distinguishing typhoid in the puerpera, from septicæmia.

Dr. Alexander Simpson called attention to the importance of distinguishing the various forms of puerperal fevers. In Edinburgh he saw many cases of typhoid after labor; these were sometimes difficult to differentiate from ordinary sepsis, sometimes distinct and with a clear history of sewage-infection. He had seen scarlatina and measles after delivery simulating septicæmia. These diseases in the puerperal woman were apt to prove fatal before their full development.

Dr. Graily Hewitt, F.R.C.P., London, England, thought that the great advance in the treatment of puerperal fever in late years consisted in means tending to prevent the introduction of septic material into the blood. Women in whom the uterus did not remain firmly contracted were the most liable to contract puerperal fever. The uterus was the seat of entrance of the poison, and in private practice the best safeguard was to keep the uterus firmly contracted. Keep the patient in as good general health as possible during the latter months of pregnancy, feed her soon after labor and keep up her strength, for where there were weakness and debility the uterine contractions were apt to be imperfect. He used antiseptic precautions and vaginal injections, with the uterine douche in appropriate cases. When the germs had once gotten into the connective tissue about the uterus, douching did no good. He insisted upon the necessity of free passage for the return flow, and advocated Budin's double-tube, which he had had made of glass, as it was then more easily examined and kept clean. In general treatment keep up the uterine contractions by various means, nourish the patient, and use stimulants *freely*.

Dr. Jones, of Danville, Ill., had never had a case of puerperal fever in his own practice. He had always used careful antisepsis, employing the mercuric bichloride, or oil of turpentine, which he considered a most excellent antiseptic. The uterine douche was a most valuable agent. Keep yourself clean.

Dr. W. W. Jaggard, of Chicago, Ill., would treat the uterus when mild infection had already begun. He vigorously protested against Madden's use of the douche daily, and was more in accord with the Vienna school, where the uterus was washed out thoroughly with a weak (two and one-half per cent.) carbolized solution, and a bacillus of iodoform weighing from sixty to seventy grains introduced. No more interference was needed. The douche was not repeated, except in exceptional cases. There was no danger from iodoform poisoning.

Dr. J. F. Y. Paine, of Galveston, Tex., in twenty-four years had had but one case of puerperal fever. The best prophylaxis was to secure firm contraction of the uterus and remove clots. The uterine douche was meddlesome and hurtful in the great majority of cases. Cleanliness, rest, quiet, good air, and good diet were all that was necessary. Quinine and iron might be given in some cases.

Dr. D. T. Nelson, of Chicago, Ill., mentioned a very grave case of puerperal septicæmia where sulphuretted hydrogen gas was used, as in Bourgeon's method in phthisis. At first the symptoms became more favorable, then diarrhœa set in. The treatment was continued cautiously, but rectitis and hemorrhage appeared, and the patient died. Here, at first, the treatment aided, but later, no doubt, hastened her death.

In a second case, in the third week of typhoid fever, a miscarriage occurred at the third month. The fever became septic, with a characteristic scarlatinal rash. The same treatment was used, employing the gas in smaller quantity, and with immediate amelioration and recovery.

Dr. William T. Stewart, of Philadelphia, Pa., indorsed Dr. Hewitt's views, and thought the liquor sodæ chlorinata, ℥ ij. to O ss., the best for vaginal douching.

Dr. Lloyd Roberts, of Manchester, England, used quinine, irrigation, and the curette when necessary. Mild cases would get well without treatment. He did not agree with Dr. Sibbett that the doctors and nurses so often carried the disease. He considered the mercuric-bichloride douche dangerous when strong; calomel was used successfully forty years ago. Could it not have had an antiseptic action?

Dr. Cameron, of Montreal, Canada, did not think we could treat the disease intelligently until we realized that purperal fever and purperal septicæmia were synonymous. There was no such thing as auto-infection; endosepsis was a pernicious myth. His views were in accordance with those of Jaggard. Antiseptic precautions were to kill or to prevent the entrance of germs. There was a very general lack of knowledge as to when or how to use antiseptic measures. The douche and curette were valuable in the right place, but harmful in others.

When you have used the douche, iodoform, and the antiseptic pad, why use other local measures? You have sterilized the canal. Food, stimulants. rest, and iron were important. There was no specific treatment. Each case should be studied. Local conditions required local treatment, general states general treatment.

Dr. Charles Warrington Earle, of Chicago, Ill.,

thought the ground very thoroughly and ably gone over by Dr. Cameron. He believed in adopting absolute antiseptic precautions beforehand. If possible, have clean, intelligent nurses. Look for the cause of the sepsis; if in the uterus, clear it out and patient would recover.

Dr. Rodney Glisan, of Portland, Ore., presented a paper on

CONSERVATIVE OBSTETRICS; WITH SPECIAL REFERENCE TO THE REMOVAL OF THE SECUNDINES AFTER ABORTION, AND TO THE TREATMENT OF THE THIRD STAGE OF LABOR.

He thought that the expectant method of treating retained secundines after abortion and the placenta after labor was unsafe in private practice, especially when the doctor resided at a distance from his patient, yet it might succeed fairly well in hospitals, under the constant vigilance of experienced practitioners.

He approves of the immediate removal of the secundines after abortion in all cases where the cervix is somewhat dilated or dilatable, as is generally the case for an hour or so after the expulsion of the embryo, and in all cases of septicæmia or dangerous hemorrhage, no matter when they occur. When neither of these accidents is present, and the cervix closed, he does not advocate the immediate and forcible removal of the secundines, but would wait a more favorable condition, when the finger could be easily inserted, moderate hemorrhage being controlled by ergot, the tampon, etc. No instrument in these cases was so safe, trustworthy, and generally useful as the finger. He adopts the bimanual method, depressing the uterus with one hand to within reach of the finger of the other, giving an anæsthetic if necessary.

In the removal of the placenta during labor the author used the Credé method, supplemented by moderate traction on the cord. He does not believe that moderate traction on the cord, when the uterus is well contracted and properly grasped by one hand externally, is attended by the least risk of inversion or of increasing the hemorrhage by a suction-like process of the placenta on the cavity of the womb. He thinks that traction upon the umbilical cord as an aid to delivery of the placenta ought not to be abandoned.

Dr. Graily Hewitt accorded perfectly with Dr. Glisan. In cases of abortion there was often great difficulty in passing the internal os. We must not expect the os to be open until the abortion had continued for some time. Instruments other than the finger were dangerous. He was much impressed with the importance of not allowing the secundines to remain long in the uterus.

Others present expressed the same views.

Afternoon Session.

Dr. Edward Henry Trenholme, of Montreal, Canada, presented a consideration of

INTERNAL UTERINE HEMORRHAGE THE RESULT OF OVERDISTENTION OF THE UTERUS FROM HYDRAMNIOS.

The author pointed out some of the causes of hydramnios and the serious results of such distention. The distention caused a deficient nutrition of the decidua, which allowed it to rupture, causing hemorrhage from the site of the tear. The blood might clot *in situ* or pass between the layers of the deciduæ. The hemorrhage began with severe pain and sense of fulness, with signs of internal hemorrhage. Cited case. We should forestall the danger by causing premature labor before the hemorrhage occurred, that is, as soon as the distention becomes excessive. Should bleeding have occurred, it is necessary to wait until the vessels have closed before we attempt treatment.

A posthumous paper by Dr. W. T. Taylor, of Philadelphia, on "Maternal Impressions Affecting the Fœtus," was read by title.

Dr. William T. Stewart, of Philadelphia, Pa., read a paper on

THE IMPORTANCE OF ACCURATE DIAGNOSIS IN PREGNANCY, WITH THE HISTORY OF A UNIQUE CASE OF RETROFLEXION OF THE GRAVID UTERUS, LABOR AT TERM.

After some remarks on the causes and necessity of the numerous cases of abdominal surgery, in which he hoped for some better means of prevention of female diseases, he spoke of the evil effects of the modern steel-clad corset, which injured the muscles of the back, forced down the contents of the abdomen, and impeded the venous return. He reported a case showing many blunders in the way of mistaken diagnosis.

The patient, aged twenty-nine, one year after the birth of her third and last child, consulted a female doctor, who told her that a tumor was growing in the posterior vaginal cul-de-sac. She consulted with several other physicians, some of them famous gynecologists, who agreed as to the nature of the "fibroid" and decided upon operation. Two days before the proposed removal of the tumor, Dr. Stewart chanced to see her and found a retroverted pregnant uterus. He advised her not to undergo the operation, and as she was not his patient did nothing more. At full term he was called upon to deliver her, and found the uterus still retroverted. The vertex presented above the brim, the body lying posteriorly. The os was dilated, but nearly out of reach above the pubes. An attempt at reposition, made with the patient in the knee-chest position, was successful. At the first pain after the reposition the membranes were ruptured, and at the second the child was born, living; weight, six and a half pounds.

Only two similar cases were recorded, in both of which the child was dead.

Dr. Alexander Simpson, of Edinburgh, Scotland, thought the case interesting, as it was extremely rare for a retroversion to persist to term.

Dr. Rodney Glisan, of Portland, Ore., related the history of a case of retroversion of the gravid uterus reduced in the knee-chest position, at the fourth month, and followed by abortion. We should always insist upon a rectification, even to the fifth month.

Dr. Williams, of Baltimore, Md., related a case where a retroverted gravid uterus, with bilateral laceration of the cervix to the vaginal junction, simulated cancer with fibroid.

Dr. John Bartlett, of Chicago, Ill., presented

A STUDY OF DEVENTER'S METHOD OF DELIVERY OF THE AFTER-COMING HEAD,

supplementing the paper with a demonstration upon the phantom.

Deventer spoke in the most confident manner of the success and safety of podalic version, and of the ease with which the head could be delivered, but did not describe his method, which, however, Dr. Bartlett had found mentioned in Smellie's work. Deventer's method was shown to consist of a reversal of the so-called Prague method, in that the body of the child was carried far backward toward the perineum, with the view of turning the occiput out from under the pubes, the anterior surface of the neck resting on the perineum. At the beginning the occiput of the child was turned forward, so as to come under the pubis as the child was drawn down. The arms were *not* to be drawn down, but left up alongside the head, being placed so as to come anterior to either parietal base. The delivery by traction backward upon the body was to be aided by pressure made immediately above the pubes, the wedge formed by the head and arms being decomposed by the

withdrawal of the larger transverse diameter of the head from between the arms, as descent of the head accompanied by extension occurs. The mechanism was only favorable when the occiput was anterior. Deventer never lost a child or tore a mother. The arms being left up, protected the neck of the child and allowed a passage for the cord alongside of them, so that haste was not as necessary as with ordinary methods, and, occupying a broad and yielding part of the pelvis, they did not obstruct delivery. The method was a plausible one, and certainly worthy of trial in suitable cases.

Professor Simpson spoke of Deventer as one of the most reliable of obstetric writers; yet, as the method would seem to endanger the perineum, he would like to see a practical demonstration of its value.

Dr. A. F. A. King, of Washington, D. C., considered Dr. Bartlett's paper the best that had been presented to the Section. In regard to the safety of the method, we must remember that the puerperal canal was elongated by the perineum, which he thought liable to be torn. However, he should describe the method in the next edition of his book.

Dr. Parkes, of Chicago, Ill., described two cases where he had had difficulty in getting down the arms, and where a decided pull backward had easily and unexpectedly delivered the head. He had not understood the matter until Dr. Bartlett's paper had made it clear.

Dr. Jones, of Danville, Ill., cited three similar cases where he had, without knowing it, used this method, with the patient on the side; the delivery being unexpectedly easy and the perineum intact in each case.

Dr. J. E. Kelly, of New York, read an elaborate paper, entitled

LITHIASIS IN PREGNANCY.

Being impressed by the frequency, during gestation, of many of the arthritic, gastric, and other phenomena which ordinarily are present in lithiasis, the author reviews in detail the relations existing between the two conditions, and concludes that the association is due to the correspondence of the condition of the blood in lithiasis and pregnancy. First considering the general pathology of lithiasis, and subsequently that of the various systems, he then investigates the phenomena of pregnancy, and indicates the influences which produce, in the maternal blood, a condition almost identical with that which is present in lithiasis, and draws a parallel between the diseased conditions most frequently observed in pregnancy and the symptoms of lithiasis. These investigations would suggest the careful supervision of the condition of the pregnant female, especially with regard to the digestive, circulatory, and urinary symptoms, and, in suitable cases, the intelligent application of prophylaxis.

Dr. E. P. Christian, of Wyandotte, Mich., read a statistical paper on

THE PROPORTION AND CAUSES OF STILL-BIRTHS.

The average for states and countries was about four per cent.; for large cities, seven per cent. His personal statistics, in a small manufacturing town, were a little less than four and a half per cent. in 1,675 labors, including 17 cases of twins.

Prominent among the causes of mortality were syphilis, intemperance, and ergot.

Professor Alexander Simpson spoke of the value of such statistical researches and of the labor they required. He strongly condemned ergot, given before the birth of the child, as being a most fruitful cause of stillbirths.

Drs. Dunmire, of Philadelphia; Pierce, of Ohio; Lester, of New York; Stewart, of Philadelphia; Robinson, of Danville, Va.; and Sale, of Mississippi, united in condemning this use of ergot.

SECTION IN DISEASES OF CHILDREN.

Thursday, September 8th—Fourth Day—Afternoon Session.

Professor Albert R. Leeds, of the Stevens Institute, New Jersey, read a paper on

THE NUTRITION OF INFANTS.

He had undertaken to find a true basis for the preparation of artificial food by analyzing eighty samples of human milk. He found that human milk differs from cow's milk chiefly in the proportion and digestibility of the caseine, which is smaller in quantity and more easily digestible in human than cow's milk. He believed that he had solved the problem by digesting the caseine by a peptogenic powder, easily obtainable and of constant strength, which, with the aid of heat, reduced the caseine in five minutes. Before this cooking, the milk had been first diluted with water in order to lessen the proportion of caseine, and then had been enriched by the addition of cream to restore the normal proportion of fat. The results of a very large number of trials, followed by careful observation, encouraged the belief that by this process the artificial feeding of infants had nearly reached perfection.

A paper by Professor D'Espine, of Geneva, Switzerland, entitled

OBSERVATIONS ON TRUE OR LOBAR PNEUMONIA IN CHILDREN,

was then read by Dr. Cordes, of Geneva. The object of the paper was to maintain that there exists in children a special form of true pneumonia, which may be called central, from its location; congestive, from the violence of the inflammatory symptoms; and abortive, when its duration does not exceed two or three days. It is found in the interior of the upper lobe, and in its upper part. As the physical signs are detected with difficulty it may easily be mistaken for some disease which has the same train of general symptoms. The microscopic examination of the sputa reveals the presence of the micro-organisms commonly found associated with pneumonia.

A fatal termination is the exception, and when it occurs is generally the result of complications. The writer detailed cases in which death had been preceded in some cases by gangrene, and in others by gray hepatization. The best form of treatment is that which has for its object the reduction of the inflammation. Tepid baths, the compresses of Priessnitz, and similar methods of combating general and local heat are to be used. This treatment is alone reliable when there is high fever with cerebral symptoms.

Dr. Henry Ashby, of Manchester, England, then read a paper entitled

SCARLATINAL NEPHRITIS FROM A CLINICAL AND PATHOLOGICAL STANDPOINT.

The paper presented the results of his own observations in the wards and dead-house of Pendlebury Hospital for Sick Children, where fifteen hundred cases of the disease had been received in the past eight years. The disease has been observed in three forms: (1) An early or initial form, not especially important when compared with the others, and (2) a variety dependent on septic changes which leaves traces in the kidneys discoverable by the microscope. It occurs in the second and third weeks. In most cases this septic inflammation of the kidneys gives no symptoms distinguishable from those of general septicæmia. It does not extend so widely in the tissues of the kidneys as to impair their functions seriously. The urine is not diminished, and general œdema and uræmic symptoms are absent. (3) Post scarlatinal nephritis, or the nephritis of convalescence, far surpasses the other forms in interest and importance. It occurs in an apparently well or rapidly convalescing child, and is the last and often fatal assault of a disease which has been

almost subdued. It occurs from the sixteenth to the twenty-fourth day. The kidneys, after this form of scarlatina, like the lungs in measles, are weakened by their efforts to eliminate poison, and are more readily affected by fibrinous or croupous inflammation. In hospital practice, at least, cases of mild scarlatina are less liable than severe cases to be followed by nephritis, which ranges in severity from cases which might easily be overlooked to those in which the uræmic symptoms are sudden and alarming. The earliest and most characteristic signs are diminished urine and puffiness of the face, which may appear several days before albumen is detected. The amount of albumen and its specific gravity vary greatly in different cases. The urine continues to diminish in quantity, and œdema of the face sets in, with vomiting and other uræmic symptoms, when suddenly a crisis like that of pneumonia takes place, large quantities of smoky urine of low specific gravity passes, and the patient is convalescing again.

A paper on the

ANATOMICAL CHARACTERS OF SCARLATINAL NEPHRITIS

was then read by Dr. Frank Grauer, of New York.

The writer reviewed the post-mortem renal conditions in the initial catarrhal nephritis of scarlatina and those which are found in the large flabby hemorrhagic kidney which belongs to septic inflammation. But he had more particularly studied post-scarlatinal or Klebs' acute glomerulo-nephritis, his observations being based on nine cases of this affection. The gross and microscopical appearances were described in detail. The kidneys were enlarged and hyperæmic, with the cortex unchanged or sometimes thickened, and the glomeruli prominent. With a low power the glomeruli are larger than normal, and with a higher power apparently bloodless.

Although he had noticed swelling and proliferation of the glomerular epithelium he did not agree with the opinion of some that the capillary circulation is obstructed through compression of the capillaries by this proliferation, because in all the specimens which he had examined the loops of the capillaries were larger as a rule than normal, showing that the pressure was from within not from without.

He believed that the capillary obstruction is due to proliferation and thickening of the endothelial cells. The hypertrophy of the left ventricle, noticed in all his cases, was due (1) to the presence of some toxic element in the blood, and (2) to obstruction of the circulation in the Malpighian bodies, which compelled the left side of the heart to do more work.

He suggested that the term glomerulo-nephritis ought to be limited to those affections in which there is an obliteration of the loops of the capillaries in the Malpighian bodies, and not applied to those affections in which there is only proliferation and desquamation of the glomerular and capsular epithelium, which are common to all forms of chronic nephritis.

SECTION IN OPHTHALMOLOGY.

THURSDAY, SEPTEMBER 8TH—FOURTH DAY—MORNING SESSION.

Professor X. Galezowski, of Paris, France, opened the session by reading a paper entitled

THE CURABILITY OF DETACHMENT OF THE RETINA.

He stated that the pathology of the disease is not entirely clear.

The writer had observed in twenty years, among 152,000 persons, 789 detachments, of which 87 were in both eyes, 63 in emmetropic and hypermetropic eyes, and 194 were traumatic; 13 occurred after extraction of cataract, 18 were syphilitic, and 4 in sympathetic affections. Tumor was found in 10 cases. Twice only he found detachment in retinitis albuminurica, although he frequently saw this affection. Cataract is very frequent in detachment of the retina.

Occasionally tearing of the retina is noticed, with the corpus vitreum introduced behind the retina, between the choroid and retina. He could say that the rupture of the retina is not so frequent, and considers it the consequence and not the cause of the detachment. Professor Graefe has said that the detachment is not curable, and the function of the retina is not restored. Dr. Galezowski had seen a case which showed alterations in the retina at the place of detachment, which had been completely cured. The patient gave the usual history of trouble with the vision, coming on suddenly and continuing for one or two or three months, with afterward recovery of sight. He explained the appearance of the fundus as seen by the ophthalmoscope, and illustrated them on the blackboard.

The conditions predisposing to detachment were said to be (1) choroiditis; (2) liquefaction of the corpus vitreum. In treating these cases he begins with antiphlogistic treatment, atropia, rest, etc., and he had in seven cases a complete cure—the retina completely adherent, and around the line of the separation atrophy, with pigment-deposit and choroiditis disseminata. The first indication is antiphlogistics. Apply every month two, three, four, or five leeches, then atropine, and warm and cold compresses alternately, and in the intervals between the leeches he applies derivative plasters. Inside of five months he has completely cured detachment of the retina. Mercury and potassium iodide are also useful where exudation is present or in cases of constitutional disease.

Fifteen years ago he proposed iridectomy to stop the inflammation of the choroid, but it did no good in that way, although it stopped the iritis. Now he proposes a new operation. He considers the exudation behind the retina as being of the same character as the effusion in pleuritis or peritonitis, and has had an instrument (which he exhibited) made to aspirate the fluid. The instrument is a syringe with a stop-cock and an aspirating-needle. He introduces the needle through the sclerotic at a considerable distance behind the ciliary body, and passes it into the globe for some distance. Then he exhausts the air by drawing out the piston. If the needle-point is too far in, no fluid appears in the barrel of the syringe, but on withdrawing the needle gradually the fluid appears, and one, one and a half, and two grams is generally obtained. There is no inflammation after the operation. By this means two out of seventeen cases operated on were completely cured, and there is a certainty of amelioration in all cases.

In old cases he introduces a curved needle from behind forward through the sclera and the detached retina, before introducing the aspirating-needle, and when the fluid is drawn off a catgut ligature is drawn through as a seton and brought tight.

Dr. Abadie, of Paris, France, spoke on the causation of detachment in myopes, setting forth the gradual stretching of the sclerotic in staphyloma and its drawing away from the retina as a cause of the detachment, with remarks on treatment.

Dr. Keyser, of Philadelphia, spoke of Graefe's method of tearing the retina through the detachment with a needle, of De Wecker's trocar, and of the double-needle method. He had never been able to get a permanently good result, although the immediate effect was sometimes very pleasing. He thought well of Dr. Galezowski's instrument, but wished to know how it would act in old cases.

J. Richardson Cross, Esq., F.R.C.S., of Bristol, England, said that there was no doubt that the subject was an exceedingly difficult one. He had treated a case with diaphoretics, had pushed pilocarpine, and used the other commonly accepted means of relief, with no change till now. He had done sclerotomy in three eyes, two in one girl. One, in a woman, did no good.

Dr. E. Landolt, of Paris, France, recognized three

kinds of detachments. The first is due to choroidal exudation; the second, detachment in myopia; and the third, traumatic detachments. For the first, the treament is perfect rest and compress dressing. He quoted a case which was cured and had remained well for three years. In the second class surgical interference may be justifiable, because there is scarcely any hope of restoration of vision in the part affected. He illustrated by a diagram his mode of operating with a Graefe knife, and remarked on the possibility of sucking out vitreous if the syringe was employed. For the third variety, traumatic detachments, there were no general rules. Some are restored with simple rest, and others resist all treatment.

Dr. E. Smith, of Detroit, Mich., had been struck with the remarks of Professor Abadie. In his first case he introduced an acupuncture needle, and the immediate result was brilliant; but the permanent improvement was *nil*. He preferred to do the operation suggested by Dr. Wolf, of Scotland, and would hope to get up adhesions to tie the retina down to the wound. Professor Galezowski's operation looks rational, if he does not puncture the retina.

Dr. Holcombe, of New York, remarked that Dr. Galezowski, when he spoke of a cure, did not mean complete restoration of vision, but only reduction of the detached portion, and its restoration to its original plane. He also described Sichel's operation.

Dr. Reynolds, of Louisville, wished to know whether it were a fact in the eye as in other organs, that frequent tapping is followed by increased accumulation.

Dr. Calhoun, of Atlanta, Ga., wished to know what advantage is to be obtained by operating in cases of this kind of long standing. The eyes are blind, and vision is not restored, and the operation may set up inflammatory action. He had done sclerotomy many times, but without satisfaction.

Mr. Power, of London, England, found it difficult to understand how there could be restoration of vision in these cases of detachment. The pigment layer is detached from the retina and left behind, and does not reattach itself again as before. He believed there might be an apparent restoration where the detached portion had hung down over the good part like a bag, and after reduction of the detachment there was an apparent improvement in that part of the retina.

Dr. Bermann, of Washington, D. C., wished to answer Dr. Calhoun's question by relating the course of a case that had come under his observation.

Dr. Galezowski remarked, in closing, that he had only done the operation in bad cases. If it had been done in all cases we might get a better percentage of favorable results. An antiseptic might be injected into the cavity. It is possible for the retina to resume its function of vision, but even if it were not, the arrest of the process and saving the rest of the vision is of value.

Dr. J. A. S. Grant (Bey), of Cairo, Egypt, then read a paper contributed by Dr. Brugsch (Bey), of Cairo, who was not able to be present, on

THE PREDISPOSITION TO GLAUCOMA.

He said that increased tension, the recognized test-symptom of glaucoma, might be produced in two ways, either by increased secretion or by retention of the secretion when normal in amount. He was inclined to think that the theory of retention was, at least in some cases, the one which appeared reasonable. It was a question whether eyes with small corneæ were more liable to be affected, and he gave some statistics which seemed to point in that direction.

The predisposition of the Semitic race to glaucoma is remarkable. In other races it occurs in the proportion of one to one hundred, here the proportion is four to one hundred. He had been surprised by finding children affected with glaucoma. The cornea of the pure Egyptian is decidedly smaller than that of other races, and he had been endeavoring to find whether the whole globe was also smaller, but his researches had been hindered by the trying climate, which produced decomposition in fresh eyes so rapidly. After iridectomy there appears to be a relaxation, and even an enlargement, of the corneal circle, as you can see if you notice that the coloboma will sometimes appreciably enlarge a considerable time after the operation.

Afternoon Session.

Dr. A. G. Sinclair, of Memphis, Tenn., reported

A CASE OF RETINAL GLIOMA ON BOTH SIDES.

A young child was brought to him with the history that some time before it was noticed not to see well, and soon appeared to be blind; then a white and somewhat lumpy appearance was observed in the pupil. Soon afterward black lines were noticed over the surface of this appearance, the retinal vessels. On examining the eye Dr. Sinclair found congestion of the conjunctival and episcleral vessels, pupil slightly dilated, tension somewhat above normal. The same appearance was observed in both eyes, except that the left cornea appeared somewhat abraded in the centre. Enucleation was proposed and was consented to. The right eye was removed, together with about one half-inch of the optic nerve, and the left eye and the whole contents of the orbit, as far as possible, without cauterization.

A careful and complete pathological examination of the right eye was made by Dr. T. Mitchell Prudden, Director of the Physiological and Pathological Laboratory of the College of Physicians of New York, who reported it as a *glio-sarcoma*.

The left eye and its appendages were examined by Dr. Carl Heitzmann, of New York, and his report came to the same conclusion. These two examinations and reports were each made without any knowledge of the other.

The case has now been observed for six years since the operation, and there appear to be no signs of the return of the disease, and the child is perfectly healthy. No heredity was discovered.

Dr. Keyser, of Philadelphia, remarked that in cases of this sort he was doubtful if the child would live more than eighteen months or two years. One case of his had lived seven years, and one died eighteen months after operation of glioma of the brain. He was doubtful if the successes were cases of true glioma.

Mr. Power, of London, England, expressed the same doubt, although he has had some successes also.

Dr. Galezowski, of Paris, has operated for the removal of this disease, and one recovered and was afterward healthy. He had only seen four cases.

Dr. D. S. Reynolds said that he thought it is a malignant proliferation conveyed through the lymph channels. When it originates in the retina he saw no reason for its not being successful. He had had a case where he had enucleated both eyes, which were invaded simultaneously and equally. There was immunity for ten years.

A propos of Dr. Reynolds' remarks as to the origin of glioma, whether in the optic nerve or retina, Dr. R. L. Randolph, of Baltimore, Md., remarked that in a microscopic examination of a gliomatous eye very recently, he found the optic nerve-fibres pressed apart by the growth, which latter extended up to the severed end of the nerve. The whole optic nerve-tissue was disorganized, and, so to speak, monopolized by the growth. He inferred that the growth must have had its origin in the optic nerve.

Dr. H. C. Paddock, of New York, read the next paper, entitled

ERGOT OF RYE IN OPHTHALMIC PRACTICE.

No mention is made of this remedy in the earliest works on medicine, and even until very lately it has been

considered to be a medicine for the obstetrician alone, and only to be good to stimulate contraction in the uterine muscle. The action of ergot is to promote contraction of the blood-vessels, as well in other organs and tissues as in the uterus, and especially in the blood-vessels of the eye. Soelberg Wells in his work mentions it as a valuable remedy in congestions, episcleritis, etc., while Hammond says it possesses the property of contracting unstriped muscular fibre. It is certain that it does diminish the calibre of the vessels, and has a good effect in obstinate affections. It is a rational remedy, and nothing more is claimed for it than its general therapeutic properties. He gave a few cases in which it had seemed to exert a marked beneficial effect.

In the case of a woman with conjunctival congestion and pain and discomfort, the whole trouble was stopped on the third day. In still another case, Mrs. B——, twenty-five years of age, there was conjunctivitis, iritis, retinitis, and ciliary neuralgia. Under ordinary treatment she improved for four or five weeks and then came to a standstill. She was then given ergot, and was discharged cured in a few weeks. In regard to the use of ergot, he begged to remark that it is a reliable drug, that it must be used in maximum doses and for several days, and that it is a good tonic; that atropia should be used in iritis, and rely on general treatment for any complications that may arise.

Mr. Power, of London, England, then read a paper written by Mr. P. H. Mules, of Manchester, England, who was unavoidably absent, entitled

EVISCERATION AND THE ARTIFICIAL VITREOUS.

The object of the paper was stated to be to lay before the Section the results of an operation which was intended to produce an improved appearance over the result in evisceration alone, with a clean cavity free from muco-pus. The mode of shrinkage after evisceration was discussed, and a blackboard demonstration of the method of operation given. The incision is made through the conjunctiva around the cornea, elliptical with its long axis horizontal. The conjunctiva is dissected back for a short distance, and an elliptical incision made through the sclera of about the same size and in the same position as that in the conjunctiva. The contents of the globe are then carefully cleared out, which is easily determined by the view of the white sclerotic in the interior of the eye. The glass ball is then introduced, the edges of the scleral wound carefully fitted together over the ball, care being taken to have no tension at the point of union, united by sutures, and the conjunctiva then brought together and sutured. There may be considerable reaction and some pain, which is treated in the usual manner. Mr. Power had performed the operation about a dozen times, and had had three bad results. One suppurated, and in two the wound yielded and the glass globe was pushed out. Catgut sutures are used.

Mr. Cross, of Bristol, England, thought Mr. Mules' operation would be a permanent one. The shield over such a globe has a better motion than any artificial eye on a natural stump can have, because the muscles have been placed in a position more nearly corresponding to that in the natural eye. It does not make any difference whether you use a glass globe or a silver or, as has been lately, a celluloid one. An advantage of this operation is that the lower lid is preserved, and is not gradually obliterated so that the shell cannot be retained. It cannot be said that Mules' operation will prevent sympathetic ophthalmia, because we cannot entirely clean out the globe. There may be affection of the lymphatics exterior to the globe already before evisceration, and it is, of course, impossible to reach them in this operation. Mules' operation is not to be compared with enucleation in sympathetic ophthalmia. We operate in sympathetic ophthalmia to save the other eye. It is not a question of appearance, but of sight.

Dr. Galezowski, of Paris, would divide the question into two parts—evisceration, and introduction of the glass ball. He saw this first fourteen years ago, with Professor Richet, in Paris. Great inflammation resulted, and it was not possible to introduce the glass ball. Enucleation was done six months after and the patient got well. He saw another case four months ago. Six months previous a good operation had been performed, but a sinus had formed in the region of the wound. Treatment with antiphlogistics, antiseptics, etc., was of no avail. Enucleation was done and all was well. One year is not long enough for a final conclusion in the matter of result. In sympathetic ophthalmia there must be danger if we leave the smallest piece in the eye, and the enucleation must be completely and carefully performed, so as to leave none of the sclerotic attached to the nerve.

Dr. Baker, of Cleveland, O., as an illustration of the ability to retain a foreign body in the eyeball with impunity, related a case which had occurred to him. A man had his eye burned severely with sulphuric acid, so that an unsightly ball was left, with no cornea. He put in a glass button like a collar-button, and the man had been wearing it comfortably ever since.

Dr. Keyser, of Philadelphia, Pa., stated that he would try Dr. Mules' method. He had had very severe inflammation occur after evisceration. To illustrate the danger of sympathetic ophthalmia, when enucleation is not effectually performed, he related a case where a small button of sclerotic was left on the divided nerve. He advised to get it all out, but it was not thought worth while, and sympathetic ophthalmia set in. He believed it was better to do evisceration early.

Dr. Dibble, of St. Louis, had seen two cases of bony deposit inside the sclerotic, and believed that in such a case the pressure of the glass ball would produce irritation and perhaps sympathetic trouble.

Dr. E. Smith, of Detroit, had seen Dr. Power perform one of these operations, and although Dr. Power had predicted considerable chemosis and severe reaction, there was no trouble whatever, and a happy healing resulted. There was not a bad symptom. He laid stress upon the fact that the edges of the cut sclerotic should just meet, not overlap or strain.

Dr. R. L. Randolph, of Baltimore, Md., read a paper contributed by Dr. H. Gifford, of Omaha, Neb., entitled

FURTHER CONTRIBUTIONS TO SYMPATHETIC OPHTHALMIA.

It related to the posterior lymph-stream, and detailed the results of experiments with injections of India-ink and anthrax. The course of the injections was ascertained by examining the eyes at periods after injection, and it was found that, even in neurectomized eyes, the coloring matters or anthrax bacilli had reached the brain from the posterior chamber; even where the cerebral end of the cut nerve contained none, showing that there is a current from the posterior part of the eye back to the brain, independent of the channels of the optic nerves.

Mr. J. Richardson Cross, of Bristol, England, next contributed a paper entitled,

RETINOSCOPY; IT PROMISES A RAPID AND RELIABLE METHOD OF ESTIMATING ERRORS OF REFRACTION, AND IS A TEST OF THE GREATEST PRACTICAL VALUE.

He stated that the full correction of the refractive error is not the one that is always most likely to be accepted by the patient, when determined by the upright or direct image method. With trial glasses it is often necessary to use atropine, but in retinoscopy he has only found it necessary to use atropine in cases of spasm of accommodation. In all other cases cocaine is quite sufficient. Either the plane or the concave mirror may be used. The production of the image at the far point of the eye in myopia is the important unit in the question of retinoscopy. The shadow observed in myopia is that of the aërial image projected from the observed eye. With illumination, no movement, and no shadow, the ob

server must be near the conjugate focus of the rays. It is a usual thing to have one constant point to calculate from and to work from, and the usual standard of a little over a metre is objectionable, because it is necessary to get up and approach the patient to make every change of glasses. Dr. Cross could use an optometer made by Doyne, which he exhibited at a distance of eighty centimetres, which obviated the necessity of moving with each change of the patient's glass. Mr. Cooper has brought out a somewhat more complicated optometer, by which you are enabled to sit at the full distance and turn the disk.

The proper point to estimate the refraction in the patient's eye is the macula, but it is not easy; the disk is easier, but not so accurate on account of the occurrence of the physiological cup so often. The writer preferred to take a point midway between the two, which could easily be done by making the patient look at the other side of the face.

The results of retinoscopy are quite satisfactory; unsatisfactory in only about ten per cent.

The differences between the result with and without atropia are slight in degree, in a spherical direction, and do not exist as to the cylindrical correction. A much higher degree of latent hypermetropia is uncovered by retinoscopy than by trial lenses.

Drs. Keyser and Reynolds rose to questions of information as to the abolition of the accommodation in the use of the method, and

Dr. Galezowski stated that he liked the method, but did not like the name. He believed the shadow to be produced by the changes in the cornea, and that the proper name is keratoscopy. An advantage is that you can make a diagnosis of the reflection without atropine.

Dr. Galezowski's assistant, Dr. Parent, had described it very accurately, and used the name keratoscopy. In proof of its being the shadow in the cornea, the best diagnosis of staphyloma of the cornea could be made by this method. There is no reason at all for the term pupilloscopy.

Dr. A. R. Baker, of Cleveland, O., also read a paper on

RETINOSCOPY.

Although retinoscopy has been extensively employed by general practitioners and specialists in England and France, it has been almost entirely ignored by German and American practitioners. While many competent observers have written extolling the method, no less an authority than Professor Hirschberg, of Berlin, remarked in a laughing manner, when the writer asked his opinion of the value of retinoscopy, "Oh, that is a lazy English method, and don't amount to much." And Dr. Loring, in his excellent work, thinks that it does "nothing which cannot be more easily and more expeditiously performed by the upright image."

Probably one reason for the rejection of this method by Professor Hirschberg and Dr. Loring is their extreme accuracy in the use of the ophthalmoscope. But this accuracy was, he believed, limited to only a very few, and it required a large amount of clinical material to continue proficient, and few, if any, master the ophthalmoscope sufficiently under forty years of age to become proficient.

In teaching the method it is better to select an emmetropic eye for the first, and dilate the pupil. A concave is more convenient than a plane mirror. If the plane mirror is used it is to be remembered that the image will move against the mirror in myopia and with it in hypermetropia, and the reverse with a concave mirror.

Dr. Burnett, of Washington, D. C., proposed the name scioscopy. He prefers the plane mirror.

Dr. Calhoun, of Atlanta, Ga., wished to know if all cases were corrected by this method so that they did not come back dissatisfied.

Mr. Cross, in closing, stated that retinoscopy was a name in general use now, and therefore it was better not to change it. He thought he would continue to use it. It certainly was not dependent on the view of the cornea, and he certainly never should call it keratoscopy.

SECTION IN DERMATOLOGY AND SYPHILOGRAPHY.

Thursday, September 8th—Fourth day.

Dr. P. G. Unna, of Hamburg, Germany, read a paper (with microscopic demonstration) on

SEBORRHŒAL ECZEMA.

The author does not consider that the diagnosis "acute" or "chronic" eczema is a sufficiently exact and scientific one. For example, there are three distinct types of infantile eczema of the face; viz., a nervous, a tuberculous, and a seborrhœal. The nervous type is seen in the eczema of dentition, appearing upon a perfectly sound skin, usually first upon the cheeks and then upon the forehead. The eruption itches in proportion to the strength of the infant and the thickness of the epidermis. The vesicles, at times, suggest in their appearance and their reddened base herpes zoster, but the marked symmetry of the lesions and the tendency to relapse would prevent such a diagnosis. Seborrhœal eczema is entirely different, in that the skin is not in a previously healthy condition. A seborrhœa has existed upon the scalp probably a few weeks after birth, which often spreads over the upper portion of the face after becoming somewhat moist. There is less itching than in the eczema of dentition. For the latter affection a zinc-ichthyol ointment is recommended to be applied and covered with a mask, together with the bromide of potassium, internally, to allay nerve-irritation. In seborrhœal eczema sulphur should be added to the zinc-ointment. Ichthyol is useless, but resorcin acts well.

Dr. Unna regards all so-called dry seborrhœas as chronic inflammatory processes of the skin, and his studies convince him that there is no hypersecretion from the sebaceous glands which can clinically be considered a dry seborrhœa, produced by a deposit upon the surface of the product of these sebaceous glands. The disease which Unna has named eczema seborrhoicum is dependent upon a condition of, or rather change in, the coiled or sweat-glands, giving rise to the secretion of fat by them. An increase of fat upon the surface indicates increased activity when it proceeds from the sebaceous glands, but when the sweat-glands pour out fat it is because of the death of their endothelial cells.

Almost all seborrhœal eczemas have their starting-point in the scalp. Three forms are described. In one, eczema seborrhoicum begins as a latent catarrh of the scalp, and goes through the stages of scaly formation and dryness, finally ending as a hyperidrosis oleosa. In the second, the scales heap themselves up between the hairs into fatty crusts, and cause the hairs to fall out. A corona seborrhoica upon the forehead, at the margin of the hair, is described, which is typical of this form of the affection.

The third form is that in which the catarrhal appearances are the most pronounced and in which "weeping" occurs, especially about the temples and eyes. This follows a simple itching pityriasis, and produces the appearances of a moist, shining eczema. A pityriasis or a seborrhœa may exist upon the scalp, while at the same time an eczema is present upon the face. The chest is affected with the crusty form almost exclusively.

Upon the arms there is a predilection for the flexor surfaces, which is explained by the rôle the sweat-glands play in eczema seborrhoicum.

Upon the legs, early in the disease, we find only the large papular and crusting forms.

Patches of seborrhœa about the mouth and nose of old people are often the starting-points of carcinoma. In almost all cases of eczema seborrhoicum of the scalp,

a simple, itchy scaliness of the ear is observed. A patch of eczema seborrhoicum is extremely stationary, remaining for years possibly without much change in size and giving rise to only slight symptoms. Beginning upon the scalp or head, as a rule, it extends to other parts below in a very gradual manner; especially locating upon the face, sternal and intra-scapular regions. This course is so the rule as to be regarded as pathognomonic, as no other eczema or psoriasis runs this course.

When the whole body becomes involved it resembles closely pityriasis rubra. Psoriasis is often confounded with seborrhœal eczema. The latter attacks the parts near the median line of the body, and is more stationary than psoriasis. It is preceded by a local seborrhœa, and the scales and crusts have a decidedly fatty character. The patches have also a peculiar configuration and spontaneously flatten out in the middle or upon one side. The prognosis is more favorable than in psoriasis. The cure is not easy, because the deep-seated sweat-glands are implicated. Sulphur is the great remedy for the disease. More active remedies for the scaly and crusty forms are pyrogallol and resorcin. Internal treatment is seldom required. Once cured, prophylactic measures, such as hygiene of the skin, must be employed.

In the discussion which followed, Dr. Zeisler said he was impressed with the closeness of Dr. Unna's observations. Such cases are frequently seen here, and are called seborrhœa. He had regarded it as a hypertrophy of the endothelium of the sebaceous glands.

Dr. Rohé, of Baltimore, said no one was in a position to call in question any statements or claims made by Dr. Unna, as similar work had not been done by others.

Dr. Robinson, the President, said there is much difficulty in classing eczema, on account of its great varieties, causes, and modifications.

As regards seborrhœal eczema, seborrhœa and eczema existing together is not uncommonly observed. He can understand how they can go hand in hand, but does not now see how the fat can have an effect as a local irritant in producing an eczema.

In closing, Dr. Unna said the point had been misunderstood; that he did not believe the fat was the cause of the irritation. He had merely spoken of the clinical side of the question. He was at the present time experimenting with some thirty cultures of micro-organisms from seborrhœa, and believed that a parasite was the cause of the irritation at a point where the fatty matter existed.

What we have called seborrhœa sicca is not a hypersecretion, but an inflammatory affection.

Warts of the scalp and of the penis he also thinks are due to a parasite which finds its pabulum upon the skin of the penis and also upon the fatty matter from a seborrhœa of the scalp.

MULTIPLE SARCOMA OF THE SKIN.

Dr. Rohé, of Baltimore, Md., presented a patient with this rare disease, characterized by the development within the skin of multiple sarcomatous tumors. The patient was a man of about thirty years of age. The tumors were of about the size of an English walnut, and were situated upon the regions of the back and shoulders, legs and thighs. He was also suffering from tuberculosis of the lungs, and had also partial hemiplegia.

Dr. A. R. Robinson, of New York, gave a report of

A UNIQUE CASE OF PROGRESSIVE MELANOSIS OF THE SKIN,

the peculiarity consisting in the progressive nature of the affection, its long duration, and the situation of the pigment. The patient was a female who, twenty-one years ago, at the age of eight, first noticed a small, dark spot upon the side of the temple. There were no subjective symptoms of pain or tingling in the part. She had suffered from chills and fever. The lesion consisted of pin-point-sized non-elevated dark or bluish-dark spots, which formed a patch occupying the whole lateral surface of the forehead.

Microscopical examination of the skin showed the epithelium to be of normal thickness. The rete mucosum contained dark-brown pigment-granules, which were also seen in lower rows of the pavement-epithelium.

Discussing the paper, Dr. Unna said he had been impressed with the blue color of the patch as represented in the colored drawing contrasting with the dark-brown color of the pigment seen under the microscope. He asked if clinically the disease presented this blue color, and whether the corneous layer was especially thick. He had never seen a similar case, and regarded it as interesting and unique.

Dr. Robinson answered that the color was faithfully represented, and that the corneous layer was not thick.

A paper was then read by Dr. A. H. Ohmann-Dumesnil, of St. Louis, Mo., on

DOUBLE COMEDO.

Dr. Dumesnil said that he had found double comedo in two and one-fourth per cent. of all male patients in hospital practice. It occurs upon all portions of the body excepting the limbs and forehead.

In regard to the formation he does not regard it as congenital, but that two contiguous comedones become fused by the absorption of the intervening septum. Multiple plugs of sebaceous matter are found, having only one central common cavity and possibly three or four external openings, all connected within. This is readily demonstrated by cutting the bridge of skin between them.

The mode of production is the same as in the single comedo, and the cavity is the analogue of the single form. This explanation he regarded as more reasonable than to suppose the existence of a number of anomalies in comedo-formation, with the necessity of having an anomaly to account for each new case.

Dr. Unna, in discussing the paper, said he believed that double comedo never developed in a totally healthy skin—that at some time there had been an inflammatory process followed by cicatrization. He had observed many cases and always found evidences of these changes, and a scar could usually be discovered.

Dr. Dumesnil did not believe in the inflammatory-process theory, and had not observed scars in many cases. He hoped someone would be able to make observations upon the disease in the formation-stage.

The next paper was by Dr. H. Watraszewski, of Warsaw, Poland, on

TREATMENT OF SYPHILIS BY INJECTION OF INSOLUBLE MERCURIC SALTS.

There is nothing new in the injection of insoluble salts of mercury in syphilis. The author has already made a communication on the same subject. He had since pursued his investigations, and has been led to give the preference to the yellow oxide of mercury. The injections are to be made about once each week, and from four to five injections have been found sufficient to cause a disappearance of the symptoms. He has never had any difficulty from abscesses.

Cases come to the special hospital for syphilis with which he is connected from all parts of Poland, having been treated by other methods. Some have the disease in its worst forms, and present all the conditions favorable for a thorough test of this treatment. The author has had results follow the injection-cure which are very favorable and warrant his enthusiasm. The feature of the method is the small number of injections required, twelve to twenty being required for a course of treatment, and only four or five to cause a disappearance of the lesions at any time present.

Once each week a Pravaz syringeful of the following solution is to be injected deeply into the tissues.

℞.	Hydrargyri oxyd. flav...	1.00 gram.
	Gummi arab.....	0.25 centigram.
	Aquæ destillat.....	30.00 grams.
M.	S.—Shake and inject.	

A Pravaz syringeful represents about four centigrams, or two-thirds of a grain.

A calomel solution made in the same way, but three times as strong, has been used by the author, who finds that while it is beneficial the reaction and irritation caused by it are much greater.

In the discussion, Dr. Gottheil, of New York, said that during the past few years we have had brought forward a variety of new methods for the injection of the mercuric salts. He thinks that patients in other countries must differ from those in America, for here they will not submit to this method. Internal treatment, he believes, must here at least remain the more common course. He asked if the injection-course was employed only in the severer cases or as routine treatment.

Dr. Shoemaker, of Philadelphia, Pa., said he had treated many cases of syphilis by this method during the past seven or eight years, and held it in high esteem, especially for old, chronic cases, where treatment had failed. He made the injections in the arm, or whereever there was plenty of fatty tissue, in the inferior scapular region and the back, and deep into the muscular tissue of the gluteal region when the patient was thin. He employed the bichloride in a watery solution, and gave as high as half-grain- and even grain-doses when the patient had been under treatment for some time, making the injections once in about three days. He had never seen an abscess result.

Dr. Klotz said he had had considerable experience with the hypodermic method, both in private and public practice, and he was surprised to hear the remarks of Dr. Gottheil relating to an inability to employ it with patients in this country. His private patients had never objected, when they were intelligent men and the process had been explained to them. In fact, when a relapse occurred they would voluntarily return and ask for it. There is some pain, but the patient will stand it, and the results compensate for it.

Dr. Zeisler was surprised to hear what Dr. Shoemaker had said. He had considered that the salts should be injected daily. The more we give at a dose the greater is the danger, and he asked if such a large dose as a grain was not very dangerous to the life of the patient. In Vienna, when he had used the method, the rule was to give one centigram in the syringeful. He thought the good feature of the method proposed by the reader of the paper was the small number of injections necessary to get the good results claimed.

Dr. Shoemaker, in answer, said that someone in London had reported fifteen hundred cases treated, in which one-third grain of bichloride had been the dose used.

He usually began with one-tenth grain, and increased it until the physiological action had been produced, or the larger doses used.

Dr. Watraszewski, in closing, said that we must not use the hypodermic method indiscriminately, but must individualize. He saw each year many of the worst imaginable cases. The patient would throw pills out of the window instead of taking them. Inunctions would be improperly and imperfectly performed; but here we have an accurate, sure, and safe means of dealing with all cases, and in severe cases the cures were much more rapid than by other means. It had proven especially beneficial in his hands in syphilis maligna of finger, and in late syphilis.

SECTION IN LARYNGOLOGY.

Thursday, September 8th—Fourth Day—Afternoon Session.

The first paper was on

NASAL FIBROMATA,

by Dr. W. E. Casselberry, of Chicago, Ill. Under this title the doctor included such neoplasms only as were of a purely fibrous structure, or where that predominated, and excluded those of a compound type, as fibro-myxomata and fibro-sarcomata. Those originating in the sinuses or naso-pharynx were likewise excluded; naso-pharyngeal fibromata are common, and tumors in the nasal cavities are prone to assume a compound type. Fibromata originating primarily in the nose are comparatively rare. In 265 cases of nasal neoplasms reported by Hopman and Schmiegelaw there is not one mentioned, and Mackenzie has reported but one of his own. Growths to a certain extent correspond in type to the structural elements of the tissue from which they originate. The fibrous layer of the mucous membrane predominates in the naso-pharynx, while the superficial layer predominates in the nose.

Fibromata may arise from any part of the nasal cavity, as turbinated bodies, septum, and floor, but the vault, especially posterior portion, is its favorite site. Local irritation, traumatism, or the presence of chronic hypertrophic process, may serve as the exciting cause, not influenced by sex or age. The duration is from one to two years. Early symptoms are of catarrhal nature, followed by obstruction and distention of the fossa. Nasal bones are forced apart, neighboring cavities encroached upon, eyes protruded, and the deformity of "frog face" may be produced. Tumor firm and non-translucent. The microscope is the only certain means of diagnosis. They are often enveloped in a smooth fibrous capsule. Microscopically the fibres are grouped in bundles or closely interlaced, with few vessels and a limited number of round or spindle cells.

Nasal fibromata tend to degenerate into sarcomata, and to recur after removal. The thorough extirpation and destruction of the base by cauterizing to the bone gives a good prognosis. The doctor gave the history in detail of a case which came under his observation. Also a systematic table of cases, giving name of operator, date, age, etc., treatment, and result.

His own case was successfully treated by taking out portions from time to time with a cautery knife and loop. For the loop he used steel piano-wire, which is from its stiffness easier to apply, and which was heated almost as readily as the platinum wire. He used cocaine, twenty per cent., thoroughly applied, and had no pain. He recommends the galvano-cautery for most cases. Accomplish a little at a time and don't aim at making a brilliant operation by removing all at once, regardless of the danger to the patient. Remove by snare if possible, so as to avoid the dangerous and disfiguring external operation.

Dr. Stockton said that a little iridium added to the platinum gave the wire the necessary stiffness, and it was more readily heated.

Dr. Casselberry, in closing, said that though there were individual peculiarities in the effects of cocaine, still much of non-success was due to solutions too weak or not thoroughly applied. Don't use a strong solution first, but weaker ones before resorting to a strong solution of twenty to twenty-five per cent.

Dr. John O. Roe, of Rochester, N. Y., then read a paper on

CHOREA LARYNGIS,

usually associated with an attack of general chorea. The author gives the history of cases where the affection was purely local as to its manifestation.

Miss S——, aged seventeen, delicate and nervous, after an attack of quinsy, developed a peculiar spasmodic

and uncontrollable cough. She would cough rapidly ten or fifteen times, with a peculiar hoarse, barking sound, after which there would be an intermission of from one to three minutes. The cough was in sound so like the barking of a dog that she was the curiosity of the neighborhood, and known as the "barking girl." It did not continue during sleep. He tried electricity and local application without effect. Hypodermics of morphia and atropia produced only temporary relief. Benefit was derived from treating as chorea. The cough suddenly ceased after seven months.

Another case, a healthy girl of thirteen, with much the same history, was mentioned, where there was no nervousness during the intermissions, which lasted one to two minutes.

He mentioned a case of a young woman of sixteen years, in delicate health, where the barking cough continued during meals, and even during sleep, without awakening her. Spray of cocaine increased the trouble. These cases were not associated with uterine trouble. On examining the larynx he found but little congestion or inflammation. Before a paroxysm of coughing there would be a peculiar twitching of the vocal cords for a while, then they would be suddenly approximated and forced apart as the cough occurred. The movements were those of chorea. As a rule, the treatment should be systemic, in addition to local applications—arsenic, valerianate of zinc, iron, valerianate of atropia, hydrocyanic acid, morphia, etc.

Dr. Thorne, of Cincinnati, O., mentioned several cases where chorea laryngis was associated with pregnancy, beginning in the second or third month, and ceasing spontaneously just before delivery. He had one case where there was such an alarming spasm of the glottis that he thought he would have to perform tracheotomy. The cords were constantly in motion between the attacks.

Dr. Lennox Browne, of London, England, had seen a case where the disease appeared with each pregnancy, and disappeared just before delivery; also three cases where it was cured by the removal of enlarged tonsils. He thinks a sea-voyage the very best remedy.

In a paper on

THE DELETERIOUS EFFECTS OF TOBACCO ON THE THROAT AND NOSE

Dr. M. F. Coomes, of Louisville, Ky., said that he considered smoking far more injurious to these parts than chewing. The smoke came into the mouth heated, and loaded with an irritating oil that would soon coat the mucous membrane were it not washed away by the saliva. Cigarette smoking is especially injurious, because the smoke is so universally inhaled, causing pharyngitis, laryngitis, and chronic irritation in the nose, not to mention the injury it may occasion to the trachea and lungs. Where the smoke is habitually expelled through the nose, we find hypertrophies, congestion, dilated vessels, and a hemorrhagic condition. The smell is impaired or destroyed. The potash salts may also have some effect in adding to the injury. Ninety-five per cent. of smokers have something abnormal or unhealthy about the upper air-passages. In bad cases he found chronic hyperæmia and inflammation of the epiglottis, with congested cords, and a hacking cough to remove the tough mucus; the voice tires easily.

A peculiar form of tobacco-habit is what is known in the South as dipping snuff. It is prevalent among negroes and women of the lower classes. They chew the end of a twig so as to form a rude brush, they then continually dip this into a small box of snuff, and rub it over gums and teeth. The gums, pushed down on the teeth, are red and inflamed, from tobacco lodged between them and the teeth, and the whole pharynx is inflamed.

Dr. Stockton thinks that as a nation we are the greatest chewers, and that chewers suffer most. He does not like potash salts used on throat or nose.

Dr. Browne smokes cigarettes, and considers them less harmful than any other form, if we don't inhale the smoke, and use a fresh mouth-piece.

The taking of snuff is an especially baneful habit, and likely to cause polypi. Singers should not use tobacco. He excludes potash salts, except, perhaps, the bromide, in treating the upper air-passages.

INTUBATION OR TRACHEOTOMY.

Dr. Max J. Stern, of Philadelphia, in a paper on this subject first gave a short history of tracheotomy from the earliest record to the present time. Some of the earlier statistics on the continent show as high as thirty per cent. of recoveries.

In the United States our results have not had such encouraging results, due probably to the difficulty of obtaining consent to an early operation.

He also gave the history of intubation from the first catheterization to the perfection of Dr. O'Dwyer's tubes.

He quoted the following statistics to show the comparative percentage of recoveries: Intubation, 26⅔ per cent.; tracheotomy, 26⅔ per cent.

The number of bad results due to accidents was very small in either case. From the following statistics it appears that up to five years of age intubation has decidedly the advantage, over that age tracheotomy has the best record:

Age.	Intubation. Per cent.	Tracheotomy. Per cent.
Under 2 years	15	3
Between 2 and 2½ years	24	12
" 2½ and 3½ "	28 7/10	17
" 3½ and 4½ "	33 1/10	30
" 4½ and 5½ "	28 5/10	35
Over 5½ years	37 9/10	39½

Some of the advantages of intubation are that it is easier to gain the parents' consent, and does not require skilled assistants or attendants afterward. Less in the after-treatment.

Tracheotomy is extremely difficult in very young children. The usual time that the tube is left in the larynx is four to ten days. As the air can reach the lungs through the proper channels, so there is less danger to the lungs.

If the child is under three and a half years, always intubate if possible; between three and a half to five, use either; if over five years, perform tracheotomy. Intubate adults. Do not perform tracheotomy if there should be much membrane in the trachea. Intubate poor patients when they cannot get good nursing.

Dr. Stern then closed by paying a high tribute to the good work accomplished by the perseverance and energy of Dr. O'Dwyer.

Dr. Charles Denison, of Denver, Col., believes in tracheotomy without tube. He showed a gag which he had modified by removing the long levers that sometimes cause its displacement. It was kept open by a ratchet catch.

Dr. Casselberry, in intubation, passes the index-finger not into the larynx, but to the arytenoid cartilages and entrance of œsophagus, instead of trying to lift the epiglottis. He advises wearing a finger-stall and practising on the cadaver first.

SECTION IN DENTAL AND ORAL SURGERY.

THURSDAY, SEPTEMBER 8TH—FOURTH DAY—MORNING SESSION.

MICROSCOPY.

Professor Frank Abbott, of New York, and Dr. R. R. Andrews, of Cambridge, Mass., were in charge of this department. Every facility was afforded the members of this Section to acquaint themselves with dental microscopy, both physiological and pathological. Among the ground specimens shown by Professor Abbott were those of carious teeth, congenital pathological enamel, hyperostosis (osteomas) of the roots of teeth, and deposits of secondary dentine. Dr. Andrews exhibited serial slides of the developing teeth, and the de-

velopment of the dental fibril. About forty negatives from his photomicrograph were especially interesting and valuable.

CLINICS.

About thirty gentlemen gave clinics in filling teeth with gold, pivoting teeth, constructing artificial dentures, and treating (surgically) diseased conditions of the gums. It would require too much space to enumerate all the gentlemen who acquitted themselves in such a creditable manner.

C. L. GODDARD, A.M., D.D.S., of San Francisco, Cal., read a paper entitled

PAIN IN THE TEMPORO-MAXILLARY JOINT CAUSED BY IRREGULARITY OF THE TEETH.

The patient, thirty years old, experienced pain in the temporo-maxillary joint during mastication, which was caused by straining the muscles and ligaments, owing to masticating with the jaw protruded. When the teeth were brought together, as in the act of eating, the incisors alone touched, and the bicuspids and molars were about one-eighth of an inch apart. The treatment employed consisted in spreading the upper teeth and thereby securing a proper articulation.

DR. E. S. CHISHOLM, of Tuscaloosa, Ala., read a paper entitled

THE INFLUENCE OF WEATHER-CHANGES ON THE HUMAN ORGANISM.

After carefully noting the influence exerted by temperature, humidity, and electricity, the author concludes that by far the greatest power over the human organism is exerted by atmospheric pressure. In support of this theory he submits two arguments. The normal atmospheric weight on man is 14.7 pounds to the square inch at the sea level. The body is sustained by an equal power of resistance, wisely provided. If the pressure be less, the surface of the body will be distended, and the superficial circulation less restrained. This change can be brought about by exposure to great altitude, as well as by natural physical causes, when the circulation will be disturbed just the same. Any undue pressure on a portion of the body may then be felt. May not this disturbance of tension on soft tissues which are fixed to the bony framework of man, or where disease has a seat in periosteal and ligamentous attachments, be liable to greater inflammation? Or when a nerve of a tooth, which in a state of health is inclosed in a bony chamber (which has no expansive liberties, nor needs them as long as health continues), becomes exposed through a small aperture? When the normal atmospheric balance is lowered, the nerve has a tendency to be drawn through the aperture and takes on inflammation, probably followed by congestion and complete devitalization.

A report from the Pennsylvania Hospital, some years ago, on the observation of barometric pressure in surgical operations, shows that in 259 operations the barometer was ascending in 102, descending in 123, and standing in 34. Fifty-four of the whole number were fatal, 11 having been operated on with barometer ascending, 25 when descending, and 8 when standing.

AFTERNOON SESSION.

The Section was honored by a visit from the President of the Congress, DR. N. S. DAVIS. In introducing him PRESIDENT J. TAFT recounted the efforts that had been put forth by Dr. Davis to secure recognition to the Dental Section. To him more than to any other man in the medical profession is due the credit for having removed the obstructions in the way of the dental specialty.

DR. DAVIS replied: Twenty-two years ago I had the pleasure of entertaining the members of the American Dental Association, then assembled at Chicago, at my house. On that occasion I expressed the hope that some day, in the near future, we might meet on equal grounds. My hopes of that day are realized to-day. At the last meeting of the American Medical Association, when the question was brought up to admit dentists holding their degree from a recognized institution, it met with no opposition. The action of that body has forever removed the obstacle which had been in your way, and you are now on an equal footing with your medical brethren.

He congratulated the members for the interest they took in the advancement of the healing art, and closed by warning them not to fall into "schools," but to meet everyone on the broad field of science.

DR. E. S. TALBOT, of Chicago, Ill., read a paper on

ETIOLOGY OF IRREGULARITIES OF THE JAWS AND TEETH.

This paper was very exhaustive and thoroughly well prepared. The writer showed throughout an intimate acquaintance with the subject, and the Section was not lacking in appreciation of his efforts.

The paper was discussed by DR. W. C. BARRETT, of Buffalo, N. Y.

A paper by Dr. J. J. R. Patrick, of Belleville, Ill., on "Irregularities," was read by title; also one by Dr. E. H. Angle, Minneapolis, Minn., entitled "Notes on Othodontia, with a New System of Regulation and Retention;" also one by Dr. L. C. Ingersoll, Keokuk, Ia., on "Inflammation of the Oral Tissues."

SECTION IN CLIMATOLOGY.

THURSDAY, SEPTEMBER 8TH—FOURTH DAY.

DR. TITUS MUNSON COAN, of New York, read a paper on

AMERICAN MINERAL WATERS, WITH REMARKS ON CLIMATE.

He discussed the subject under four topographical headings: Springs of the Atlantic, the Southern Central, the Northern Central, and the Western or Pacific States. He called attention to the fact that much of the Eastern area of the country was of earlier formation than that of Europe; that, in fact, this part of the New World was, geologically speaking, the Old World, and not the New. This fact explained the comparative absence of thermal springs in the East, while the Western area, including but thirty-nine per cent. of the total area of the country, yet contained eighty per cent. of the known thermal springs. The range of the American mineral springs in their chemical constitution is very great, and their curative waters are as important as those of Europe. In some parts of the country, as in New Mexico and in Nevada, it is often easier to find an alkaline or a saline spring than a stream of pure water. Dr. Coan gave a rapid survey of the subject, mentioning the typical springs which are suitable for the cure of particular diseases, and at which good hotel or other accommodation can be found. He remarked upon the comparative absence of well-appointed *sanatoria*, or cures, at the American springs, and the consequent lack of systematic treatment, leading both patients and physicians to underrate the curative value of spring treatment. Climate is an adjunct element of the utmost importance in spring treatment; and the best climate in the country is that of California and Oregon. The climate of the Hawaiian Islands is probably the most equable that is known, at the comfortable range of about 70° to 80° F., and those islands are destined to become a health-resort for Americans.

DR. RICHARD J. NUNN read a paper entitled

A CONTRIBUTION TO THE STUDY OF CLIMATIC AND OTHER PECULIARITIES OF LOCALITIES WHICH DETERMINE EXEMPTION FROM ENDEMIC PLAGUES.

The object of Dr. Nunn's paper was to determine whether the extraordinary exemptions from certain diseases in Savannah are due to any special topographical or sanitary conditions in that city.

Vesical calculus, typhoid fever, typhus fever, puerperal fever are absent; Asiatic cholera visited the city only once (1866); diphtheria and exanthematous diseases are mild; membranous croup is exceedingly rare; cholera infantum is mild and exceedingly rare; cerebro-spinal meningitis has appeared but once in the city; sunstrokes are very unusual; erysipelas is not common; yellow fever has occurred but four times as an epidemic; dengue is infrequent.

The varying death-rate between the white and black races was referred to. Between 1856 and 1860 the black mortality never reached that of the whites, while since the war the death-rate among the negroes has reached double that of the whites. The changed social condition of the black race is supposed to be responsible for this variation. Formerly the negroes were almost entirely exempt from consumption, now they are extremely liable to this disease. The same may be said of syphilis.

The following papers were then read:

"The Injurious Effects of Overcrowding in Cities," by Dr. A. Wernich, of Coeslin, Germany; "The Thermometer as a Climatological Instrument," by Major Charles Smart, Surgeon, United States Army; "Vital Statistics and Medical Geography," by Alfred Haviland, M.R.C.S., of London, England; "Western North Carolina as a Health Resort," by Dr. Henry O. Marcy, of Boston, Mass.; "Therapeutic Influences of the Climate of Southern California," by Dr. P. C. Remondino, of San Diego, Cal., and "Short Notes on the Mineral and Thermal Springs of California," by Professor W. F. McNutt, of San Francisco, Cal.

SECTION IN GYNECOLOGY.

THURSDAY, SEPTEMBER 8TH—FOURTH DAY—MORNING SESSION.

DR. EPHRAIM CUTTER, of New York, read a paper on

GALVANISM FOR UTERINE FIBROIDS.

The paper was divided into Expectations, Realizations, Answers to Critics, Conclusions.

EXPECTATIONS.

August 21, 1886, the first American operation was performed, simply to arrest development of the fibroid. It was participated in by Dr. W. S. Stoveham, of Massachusetts (see *American Journal of Obstetrics*, New York, February, 1887, p. 120).

Dr. Gilman Kimball was present, August 29, 1887, and operated the second time. "So far as the priority is concerned, I am willing to give it to him, for I will have no question of honor between him and me."

The idea of using common needles was scouted at once by their unsatisfactory performance. Dr. Kimball said he would have nothing to do with the operation unless better needles were provided. Dr. Cutter invented one plated with gold and shaped like a corkscrew, which proved a useless device. The so-called Cutter needles were then produced. Whatever has been or may be said of them, they were satisfactory.

REALIZATIONS.

After sixteen years, besides the expected arrest of development in a large majority of the cases, there have been: 1, entire cures; 2, great diminution of the growths; 3, relief from pain and hemorrhages; 4, attention to the operation by the profession; 5, about four hundred cases of operation reported, besides many scores not reported; 6, the variation from galvanism to faradism, in the mode of application, in the batteries, in the duration of the application, in the kinds of electrodes, in the discovery of instruments for mensuration; 7, the operation has been widely published and has become pretty well known; 8, uterine fibroids are no longer *opprobria medicina*.

When the first operation was done there were no ampèremeters, only voltameters, which are measures of electro-motive force. It was not claimed that the milliampèremeter cures; it only measures. He only objected to the doctrine that no operation could be done without measurement, not to measurement itself.

APOSTOLI'S CRITICISMS.

Dr. Cutter distinguished between him and his sayings; he knew him for the work he had done, and replied to him in no spirit of malice.

CONCLUSIONS.

1. When an untried operation is purposed it is not wise for those whose opinion is asked as experts to say it cannot be done.

2. Best to give all due credit for what they do.

3. In performing this operation use common-sense, and not blindly follow anyone's method unless indicated by the strongest signs.

4. Hereafter any physician who says uterine fibroids are hopelessly incurable is not sustained by the facts and evidence.

DR. A. LAPTHORN SMITH, of Montreal, Canada, was sorry that Dr. Apostoli could not defend himself in the English language against the criticisms in the paper of Dr. Cutter. Most uterine fibroids are situated posteriorly, and hence are easily reached and treated by negative galvano-puncture. He had been deluged with questions about this treatment since the reading of Dr. Apostoli's paper and his own. As to the question, Can fibroids be treated without puncture? he would refer them to Dr. Martin's paper, which was on this subject. Apostoli never dares to make an examination without first washing out the vagina with a bichloride solution (1 in 1,000, 2,000, or 3,000). He cures subinvolution, and with the positive galvano-cautery does away with dilatation in very many cases of dysmenorrhœa. Gentlemen who make their living by the removal of the ovaries will lose their occupations when electricity is more in vogue.

DR. F. H. MARTIN, of Chicago, said he knew it to be utterly impossible for Dr. Cutter to get any current at all through the battery described by him.

DR. KIMBALL, of Lowell, Mass., who was introduced by THE PRESIDENT as a pioneer in the treatment of fibroid tumors by electricity, gave his experience.

DR. GARRETT, of Boston, who was also introduced as a pioneer, gave his testimony, thus completing the programme of the "pioneers' picnic."

DR. APOSTOLI, of Paris, spoke in defence of his system. He wished to give Dr. Cutter all credit for his investigations; but now that we have the means of measuring electricity, a measurement made definite by the Electrical Congress of Paris, there is no excuse for using it haphazard and everyone should use it rationally.

DR. SMITH, of Montreal, said there were a hundred little details, which it was impossible to explain in the short time allowed.

DR. CUTTER, of New York, called his son to testify that he got a current in his battery, which the son did, reciting a case. Dr. Cutter said he did not want to be put down as a fool, and told to do this and to do that. He asked Dr. Apostoli if he had cured any case so that the tumor had entirely disappeared.

DR. APOSTOLI replied that he cures the cases symptomatically, the patient does not know that she has a tumor.

AFTERNOON SESSION

DR. AUGUST MARTIN, of Berlin, Germany, read a paper on

THE VAGINAL TOTAL EXTIRPATION OF THE UTERUS FOR CANCER.

Freund inaugurated the extirpation of the cancerous uterus ten years ago. Sufficient material is now at hand

to decide the two following questions, which may legitimately be asked concerning every new method of surgical treatment:

1. Is this operation practicable with such immediate success that it promises good results in the hands of others than a few specially successful operators?

2. Does the extirpation of the cancerous uterus give permanent results which force us to recognize that this method is superior to any other treatment of cancer employed up to the present time?

In seeking an answer to the first, if they examined the literature, they would be struck with the fact that only meagre and isolated reports about this operation could be found in English and German medical journals. Vaginal extirpation had obtained decided recognition in Germany. In this country the purely vaginal operation of Czerny and Billroth and Schroeder had been adopted instead of the procedure of Freund, which was a combination of abdominal and vaginal operations. The results of the same have improved noticeably with increasing exercise and experience.

In 1881 Olshausen collected 41 cases, with twenty-nine per cent. mortality. In 1883 Sanger, 133 cases, twenty-eight per cent. mortality. In 1884 Engstrom, 157 cases, twenty-nine per cent. mortality. In 1886 Hegar, 257 cases, twenty-eight per cent. mortality.

Through the courtesy of these operators, who to his knowledge commanded the greatest amount of material, and, at his request, placed at his disposal the results up to the end of the year 1886, he was able to present the following:

Up to the end of 1886 these total extirpations had been performed on account of carcinoma uteri: Fritsch, 60 times, with 7 deaths; Leopold, 42 times, 4 deaths; Olshausen, 47 times, 12 deaths; Schroeder (Hofmeir), 74 times, 12 deaths; Staude, 22 times, 1 death; A. Martin, 66 times, 11 deaths. Total, 311 cases, with 47 deaths, or 15.1 per cent.

Were they not justified in assuming that this

RATE OF MORTALITY WOULD DECREASE

with more experience, as shown by the published tabular results of each of these operators? Already the total extirpation of the uterus for cancer showed better results, so far as immediate mortality is concerned, than removal of the breast for cancer.

For the latter, Kuster, at the Twelfth Meeting of the German Surgical Society, in 1883, published 778 cases, with a mortality of 15.6 per cent. Who would hesitate to propose to perform the amputation of the cancerous breast so soon as the diagnosis is established?

He did not hesitate to answer his first question in the affirmative, and to claim for this operation of the vaginal total extirpation of the uterus a full and equal rank among all methods for the treatment of cancer of this organ.

For an answer to the second he would make use of the relatively small, but very accurately reported cases of Schroeder, collected by Hofmeir, and those of Fritsch, Leopold, and himself.

They show that the permanent results of vaginal total extirpation in this relatively short period of observation were no doubt equal to the best results of carcinoma operations of other organs.

The author up to the end of 1885 operated on 44 cases. Of these relapsed 18, or 29.7 per cent.; recovered 31, or 70.3 per cent.

Was there any other method of treating cancer which with so small mortality could show equally good results? There was no other mode of treating cancer of the fundus and those forms of diseases of the cervix in which the mucous lining of the cervical canal was the point of origin, or in which there were carcinomatous nodules in the tissues of the neck. There was no room for discussion except in epithelioma of the portio vaginalis arising from the surface of the cervix, that is, from a surface covered with flat epithelium and containing very few glands.

He agreed with Fritsch that the observation of cases of progress of the disease in isolated nodules in the mucous membrane up to the fundus, in cases of carcinoma colli, is sufficient in itself to show it was erroneous to claim that in carcinoma of the cervix we should try to save the body of the uterus. Binswanger and P. Ruge have described such well-marked cases.

The possibility of a subsequent pregnancy was not excluded in cases of high excision; but Hofmeir himself declares that pregnancy is a very serious danger in carcinoma. Therefore he was convinced that it is much better to immediately perform vaginal total extirpation in these forms of epithelioma of the cervix. The sooner they operated the more surely they might hope to save their patients from the sad fate of death by cancer. The greater the experience with vaginal total extirpations the more has the rule been proved that we should perform the operation only when the vicinity of the uterus is entirely free from carcinomatous infiltration. All attempts to enlarge the boundaries of the operation in this direction had failed.

The technique of the operation had undergone only immaterial changes, as is shown by the results of operators using different methods. It was irrelevant whether the uterus be removed by an incision made in front or at the side of the neck, or behind it. It was of little importance whether hemorrhages be prevented by stitches introduced before the incision, or whether each separate vessel be seized and tied as it bleeds. It was immaterial whether the uterus be turned over or removed by drawing it down and freeing it; whether the opening in the floor of the pelvis remain open or be closed, or be drained either with the iodoform gauze or with a tube.

If it were easily practicable he advised that the ovaries and tubes be also removed. It was immaterial whether the wound be sutured or not. It was wonderful what little impression the operation made on the patient. One could liken her very much to a puerperal woman.

Bleeding must be stopped, at all events during convalescence, and the parts as much as possible kept at rest. Washing out the peritoneal cavity does not work favorably.

The papers of Drs. Martin and Jackson, on "Hysterectomy for Uterine Cancer," were now opened for discussion.

Dr. Martin, of Berlin, said he was accustomed to prepare his patients for operation with the most thorough antiseptic vaginal injection. He then described most minutely his method of operating. He very frequently opened Douglas' pouch at one stroke of the knife. We then see the posterior fornix and cut carefully, paring with the finger-nail. When the perineum is opened he introduced one finger into the peritoneum, and, having warm water running over the surface, did not use sponges and sutured the vagina to the peritoneum. When he had freed the broad ligament he cut it from the uterus and generally had no hemorrhage. He then proceeded in like manner on the other side, till he had the broad ligament severed there also. Up to this stage there was very immaterial hemorrhage. He then commenced on the bladder—freeing it with the forceps or the knife. After it was freed he united the cut border of the vagina with the peritoneum, just as he did before. He was accustomed to put a drainage-tube into the peritoneum, consisting of india-rubber. He thought it did good, although he confessed that he believed that a case which is not infected should be closed up. Yet he had had such good results from this that he still used it. There were various gentlemen present who had seen him operate, and who could testify that he lost a very small amount of blood. Of course there are cases where a loss of blood is necessary from the existing conditions. The operation was yet new, it had only been

done for six years, and he thought we would improve on it very much.

Dr. D'Arnay, of Hungary, gave a history of his experience with twelve cases. Out of these twelve cases only two are now living, after a period of three or four years. As to the operation, he thought that the best we could do was to close the opening into the pelvis, and fill the vagina with iodoform gauze, and let the patient alone. As to Dr. Jackson, he thought he was on the wrong road with his statistics. Statistics deal only with quantity, not with quality. If there are one hundred persons on a ship, possibly he could save only one of them. Should he not save this one? Certainly. Patients suffering with cancer of the uterus are shipwrecked persons, and sure to die a most painful death. We can save a number of our patients, and those who die usually die in a short time, and comparatively comfortable deaths. Humanity demands of us that we do the operation of vaginal hysterectomy in all cases in which we can remove all of the diseased tissue.

Dr. A. P. Dudley, of New York, wished to enter a plea for vaginal hysterectomy for uterine cancer in America, and point out why the operation had been less successful here than in Germany. Martin had sixty-six cases, with eleven deaths. In a paper read by the speaker some time since, he reported sixty-six cases with thirty-four deaths. These sixty-six cases, however, were divided between thirty-four operators, and there lay the difficulty. Experience is a good teacher, and practice makes perfect. The child must creep before it can walk, and the surgeon must have a fair trial, especially in America. As in the case of ovariotomy, which originated in America, our surgeons are almost flocking to Europe to learn how it is done. The amount of pain and suffering in the death of the patient is one of the points which should induce us to try this operation, The doctor then showed some pictures on a screen, relating to the discussion.

Dr. Nunn, of Savannah, Ga., said that there was always a starting-point to cancer. It is generally due to neglect of fissures or some other irritant, arising consequent to parturition. In his own practice he has his patients report to him occasionally after delivery, and sees that they take care of themselves properly, and he has not had a case of cancer among his own patients.

Dr. Graily Hewitt, of London, said that the whole civilized world, and the uncivilized too, were under obligations to Dr. Martin and his colleagues for their work in this line, having advanced the operation to its present state. In a discussion in the London Obstetrical Society, a few years ago, he was the only one who refrained from condemning the operation. He thought it should be done in properly selected cases, by gentlemen of experience.

Dr. A. Reeves Jackson, of Chicago, thought it wrong to attempt to reason against facts, as well as difficult. His paper was based on facts founded on the results of Gusserow, Paget, and such men. These gentlemen had estimated the duration of life, in those women suffering from uterine cancer, to be twenty-one months as an average. If this be true, then my calculation as to the duration of life will not be denied. The average duration of life of women operated upon is fourteen months; this difference in the aggregate amounts to nearly three hundred years of grand total loss of life. Does anybody allege that it has saved life? Dr. Martin claims that the operation should be done only when the disease is limited to the uterus. How does he know the case was limited to the uterus? Because it did not return? Baker, of this country, by his high operation, has sixty per cent. of recoveries, which is far better than Martin's.

Dr. Martin replied that he knew that a cancer was limited to an organ by its having a layer of entirely healthy tissue around it.

SECTION IN ANATOMY.

Thursday, September 8th—Fourth Day—Morning Session.

The first paper presented was entitled

THE FUNDAMENTAL ANATOMICO-MECHANICAL CONSIDERATIONS UNDERLYING THE SUCCESSFUL TREATMENT OF DEFORMITIES, DISEASES, AND WEAKNESSES OF THE SPINE,

by Milton Josiah Roberts, M.D., etc., of New York. He began by saying that he had spared no time, labor, nor expense in studying this subject thoroughly, by testing all known methods, and felt that he could offer his results with some satisfaction to the Section. The corsets for the arrest of Pott's disease and other spinal troubles were made of a fine wire thread which was carefully woven over a plaster cast of the patient's body, so as to secure an exact adaptation. The great problems to be solved were —how and where to get hold of the body to support it without irritation, and how best to apply any remedies necessary. These problems, he thought, were simply mechanical. Bone should be the supporting point. He spoke of the great advantage of these wire corsets over the heavy and clumsy plaster-of-Paris jackets. He thought there was a great want of proper description of how to apply these apparatus on the part of writers and lecturers. He mentioned, also, the ease with which these wire jackets followed the chest-walls during respiration. He had found no brace so good for the support of the head as the one which went over the head. He showed several fine specimens of Pott's disease and other spinal deformities, and also many well-executed photographs, drawings, and models, all his own work.

Dr. William J. Herdman, of Ann Arbor, Mich., spoke of the great advantage of Dr. Roberts' wire jackets over the old plaster jackets, and very wisely insisted that such apparatus could only be applied by one thoroughly interested in the subject and ingenious and skilful.

Dr. Max J. Stern, of Philadelphia, Pa., then presented a specimen of

AN ANOMALOUS MIDDLE THYROID ARTERY,

the knowledge of which was of surgical importance in tracheotomy. He thought it was the first of its kind made public.

Dr. William J. Herdmann, of Ann Arbor, Mich., had seen several such anomalies, and thought it not uncommon; but had never published his cases.

Afternoon Session.

Dr. W. X. Sudduth, of Philadelphia, Pa., then read a paper on

DEVELOPMENT OF BONE,

in which, after defining the terms ossification-bone and osteoblast, he laid down as the result of his study of developing bone that the white blood-corpuscles were the basis of all the connective-tissue group. He emphasized the point that the osteoblast did not become calcified. In the process of calcification the secretion took place around and not in the cell, the calco-spherules joined, and solid bone was formed. This deposit of bone-salts took place in the interstitial protoplasm. As the ossification began, the first deposit of bone was at the periphery of the system, and as it approached the centre it was self-limiting. As calcification progressed the osteoblast decreased in size and its envelope grew thicker. He quoted several authorities and their definitions of the different kinds of bone according to their development. His own definition of bone was that it was an aggregation or conglomeration of calco-spherules. His own division of bone according to its development was:

(1) Interstitial; (2) intermembranous; (3) subperiosteal; (4) intercartilaginous.

By interstitial bone he meant those bones which were not preformed in cartilage and in which ossification took place prior to birth. The paper was illustrated by many microscopical specimens of developing bone, which were beautifully stained and mounted.

Dr. N. Stamm, of Fremont, O., then read a paper entitled

ANATOMICAL POINTS OF VALUE IN THE DIAGNOSIS AND TREATMENT OF SOME OF THE JOINT AFFECTIONS.

He first described the anatomy of the synovial sac and proceeded to speak of some of the inflammatory and tubercular affections of the joints, confining his remarks to the knee- and ankle-joints. He reviewed the etiology, pathology, and bibliography of the subject and then laid down the rules of treatment, the basis of which was rest and fixation.

Dr. Benjamin Lee, of Philadelphia, Pa., then read a paper entitled

CASE OF DEFORMITY OF THE SPINAL COLUMN PRODUCED BY MATERNAL IMPRESSION ON THE FŒTUS,

in which he related a case of kyphosis supposed to have been caused by maternal impression.

In the discussion which followed, Dr. Joseph N. Dickson, of Pittsburg, Pa., and several others were of the opinion that many cases occurred in which the maternal impression had no visible effect upon the fœtus, and thought that if statistics of all such cases could be collected a small proportion would be found to be so affected.

SECTION IN PSYCHOLOGICAL MEDICINE.

THURSDAY, SEPTEMBER 8TH—FOURTH DAY.

Dr. S. S. Bishop, of Chicago, read a paper on the

PATHOLOGY OF HAY FEVER.

The doctor believed full reliance could never be placed in the pollen theory. The very fact that hay fever recurred upon the very same day of the year in many cases, irrespective of the late or early coming of the seasons, was a proof against it. He believed it was of nervous origin, and would designate it by the term nervous catarrh.

Dr. Channing thought it should hardly be dignified with the term of a neurosis. He supported the pollen theory, and stated that removal to mountains or sea-shore resorts was an effectual remedy in the cases he had seen.

Dr. Brush did not believe in the pollen theory. He had himself suffered from hay asthma at different times in the summer, from July until autumn.

Dr. Hurd believed in the neurotic origin of hay fever until the present season, which he said had been an unusually hard season for sufferers from nervous troubles. As a matter of fact, hay-fever invalids had had little or no discomfort. He believed ragweed to have a potent effect in causing hay fever, and stated that in Michigan this year ragweed had not flourished, and the result is seen in the little discomfort from hay asthma.

Dr. Andrews believed we could point to no one cause for hay fever. Different causes affected different people. He would ask Dr. Bishop for his views on the treatment of hay fever.

Dr. Bishop stated that people of a particularly nervous temperament were the greatest sufferers from hay fever, just as they were often great sufferers from peculiar troubles of nervous origin. He had heard a patient declare that eating strawberries would throw her into convulsions. Hay fever is most prevalent, he said, during the most depressing season of the year. He could not believe in the pollen theory.

As to the treatment, he would say that it was more palliative than curative in the majority of cases. One physician of his acquaintance had procured benefit in forty-five cases by the application of the galvano-cautery to the septum nasi. He had obtained either partial or complete relief.

As to his own practice, he had found the use of a combination of sulphate of morphia and atropia, in the proportion of one-fiftieth of a grain of atropia to one-half grain of sulphate of morphia, to have a most beneficial effect. Not that he would give half a grain of morphia to patients at once. He had made this combination of morphia and atropia into small tablets, and gave them in the proportion of one-eighth of a grain of morphia to a proportionate amount of atropia.

In his experience, if a patient would take one or two of these tablets immediately upon feeling the first symptoms of hay fever, it would usually abort the attack. He had always given as large a dose of morphia as he thought the system of the patient could stand, in order to make an impression at once upon it. He had also found taking cool drinks or ice-cream immediately before going to bed to be of great assistance in warding off nocturnal attacks.

If a patient keeps himself cool throughout the day, too, there is less danger of his being attacked. Quinine deadens sensibility, and is of use, but will not always avert an attack.

The next paper was by Dr. Elliott, of New Haven, Conn., on

THE TREATMENT OF NEURALGIA

by the general practitioner.

Dr. Crego did not like to hear that Dr. Elliott prescribed so much morphia in the treatment of neuralgia. It is the duty of physicians to use as little morphia as possible. Arsenic and iron should be prescribed and electricity be used as often as practicable.

Dr. Duquet thought well of the hypodermic injections of chloroform in sciatica. Injections of twenty drops very deeply into the muscles, just at the beginning of an attack, he had found of great value. He did not share in Dr. Crego's sweeping denunciation of morphia.

Dr. Heber Ellis thought highly of hydrochlorate of ammonia, which he said had been used with success in Germany, and which he had himself found valuable. He could not so highly recommend quinine. He had seen cases of chronic deafness result from its constant use.

Dr. Girstrom, of Sweden, had found massage of great value in the treatment of neuralgia.

Dr. Brower, of Chicago, discouraged the indiscriminate use of morphia and quinine. He had seen too many morphia *habitués*, whose habit had commenced in this way, not to feel like protesting against their too frequent use. You obtain a great amount of *éclat* for instantly relieving your patient, but you do him, in many cases, far more harm in the long run than good.

Dr. Clark, of Toronto, said he took good care when prescribing morphia, in all cases, to conceal from the patient the fact that he was giving him morphia. Many times when prescribing it internally, he gave it with some medicines of such nauseating bitterness that the patient was rarely inclined to ask for its like again. He believed that the treatment of neuralgia should depend upon the causes of the disease.

Dr. Andrews recommended the use of cod-liver oil in the treatment of chronic neuralgia. In an emulsion aided by phosphites, iron, arsenic, and other tonics, it was excellent. The use of the hot-water bag, too, was very useful.

Dr. Russell read a paper entitled

BORDERLAND OF INSANITY,

endeavoring to show that epilepsy and kindred diseases did not necessarily produce mental weakness. He introduced Julius Cæsar, Napoleon, Martin Luther, Cowper, and others.

Dr. Gundry said we had no exact facts of any kind

as to the nervous troubles from which Cæsar, Napoleon, and others were said to suffer.

Dr. Porter hoped the suggestions of Dr. Russell's paper would be followed. In too many cases were the obvious signs of insanity not heeded, and oftentimes a patient is permitted to remain at home, passing without treatment into a case of chronic insanity.

Dr. Ellis, of London, thought that the course pursued in the past, both in England and America, in the commitment of patients to asylums, was not such as to induce the friends of a patient to place him in an asylum, unless, in many cases, absolutely compelled to do so. Happily, in England a new plan had been adopted. A medical man receives one or two patients into his house, and these patients are seen regularly by the commissioners and receive proper inspection. They secure the benefit of change of air, of environment, of diet, and are at all times under careful personal observation by the physician.

When a patient is cured he retires quietly to his home, and does not retain with him the unpleasant recollection that he has been committed to an asylum—a humiliating thought under the best of circumstances. The great objection to this plan was the expense involved to the patient.

Dr. Fisher read the next paper, written by Dr. Edward Cowles, entitled

NURSING REFORM,

which detailed the success which he has had at the McLean Asylum in training his nurses, and of the improved *esprit de corps* among the attendants and patients.

Afternoon Session.

Dr. W. W. Godding presented a paper entitled

INSANITY AS A DEFENCE FOR CRIME.

He denied that the test of a knowledge of right and wrong was a correct one to apply in determining the criminal responsibility of lunatics. Judges in the United States have made but a metaphysical study of insanity. They should obtain clinical knowledge of cases by visiting a hospital for the insane, and thus get rid of the idea that lunatics acted reasonably in regard to their acts. He believed that the New Hampshire ruling as to insanity, which Judge Cox on the Guiteau trial rejected as heresy—namely, that all questions on insanity were facts for the jury to determine, and not rulings for the court—would one day prevail.

Dr. Savage then opened the discussion upon

SYPHILIS ASSOCIATED WITH GENERAL PARALYSIS.

General paralysis is not a definite disease, but a degeneration. Syphilis seems to have a distinct and special tendency to cause degeneration of the nervous structure. There is a difference in statistics as to the numerical relations between syphilis and general paralysis. He believed that very many general paralytics had had syphilis, and that usually general paralysis was due to syphilis. That from family histories other causes were as efficient without general paralysis, and caused general paralysis.

He could not distinguish between general paralysis due to inherited weakness and that due to syphilis and that from any other cause. General paralysis associated with syphilis might begin in the brain or cord. Acute general paralysis might suddenly develop in cases of chronic syphilis. Dr. Savage gave a very interesting case of this form, in a man in whom syphilis had not manifested itself for several years, and in whom general paralysis had suddenly developed and gone on to a fatal termination in a very brief time.

General paralysis with syphilis may run an ordinary course in every way, having no special cranial-nerve or other complication. In some of these cases the patients have a worn aspect, with capillary congestion about the face. There are very many cases in which the following history is given—viz., that there has been a cranial-nerve lesion which has improved under specific treatment, and, later, symptoms of progressive degeneration have set in.

The nerve-lesion may be motor or sensory. He had had cases of ptosis followed by general paralysis. and of giddiness followed by general paralysis.

In cases of general paralysis associated with syphilis, some are spinal, and of these some are ataxic; others have degeneration in the lateral columns, with spastic symptoms. There may be eye troubles with either. The course which cases of general paralysis with syphilitic histories run differs in some particulars from others; it appears to be more subject to remission, and even to apparent cure.

The Section next listened to an address by Professor Mendel on

MORAL INSANITY.

He maintained that the term should be stricken from the nomenclature of mental diseases. Mental imbecility or paranoia, or something more tangible, should be adopted.

Dr. Savage said there were certain terms which we were at times obliged to use provisionally, and this was one of them. There were people with moral scars who did not deserve the term paranoic nor imbecile, unless you extend the term unduly. Of course I agree with Professor Mendel that we must be careful not to use in courts of law terms that we cannot define, but I still believe we shall have to use the term moral insanity.

Dr. Hughes did not question the existence of moral insanity, as described by Pritchard. He would substitute for the term moral insanity, because of the difficulty encountered in explaining its meaning in courts of law—"a state of imbecility associated with congenital mental defect."

The discussion upon the relation of syphilis to general paralysis was then resumed.

Professor Mendel's views were presented in German.

Dr. Mickle had often seen cases due to syphilis present the same symptoms as the ordinary every-day case of general paralysis. Other groups were those presenting at first local motor symptoms, local motor paralysis, or sensory symptoms, as well as nocturnal headache. There are local unilateral spasms, followed by paralysis. These paralyses clear up sometimes, but their more usual course is to gradually take on a complete hemiplegia. Such patients often present local symptoms late in the course of the affection, such as ocular paralysis. Then when you come to the necropsy, there is in this class of cases a pachymeningitis—a local one—affecting the dura on one side. Thickening is found on one side, and there is adherence of the meninges to the surface of the convolutions and erosion of the convolutions, which is so common in general paralysis.

There is often a somewhat diffuse yet circumscribed sclerosis affecting a greater or less tract of the cortex of the brain. That he had frequently found existing upon one side chiefly, or upon one side only. There is another group of cases of brain-syphilis and general paralysis. The affection often simulates its demented form. There are probably epileptiform convulsions, a local paralysis, more or less marked, and sometimes a monoplegia. Such patients often die in epileptiform seizures, and in an epileptic status. At the necropsy you find the cerebral blood-vessels, particularly those of the circle of Willis, with their coats enormously thickened. Then they exhibit, sometimes, growths that are really syphilomatous, really a gumma of the arterial coat. At such times there is a diminution of the lumen of the vessels. This explains the absence of degeneration in these cases.

In consequence of syphilitic arteritis affecting the walls of the large blood-vessels, and in consequence of

the syphiloma affecting their coats, causing thickening of the walls, there is an obstruction of the walls and a tendency to thrombosis, and as a result we get local softenings, and these give symptoms of ordinary paralysis. In these cases there are gummatous infiltrations affecting other than arterial walls.

Dr. Down said that in his experience in London hospitals he had come to the conclusion that nearly all cases of locomotor ataxy were of syphilitic character, that they all responded to specific treatment, and that they are, as a rule, syphilitic. He had had an opportunity of studying the question whether there was any connection between locomotor ataxy and general paralysis of the insane. He cited the case of a chaplain in a Welsh prison, who had come under his observation suffering from locomotor ataxy of a progressive character. There was nothing else indicating trouble, but this man, after ten years, had some exaltation of mind, which rapidly increased, and he soon became a general paralytic and died in about eighteen months after the first attack.

Dr. Yellowlees said one often sees cases of general paralysis in which there was constitutional syphilis running an ordinary course. He thought one should be careful as to stating the effect of syphilis in the history of the disease. He agreed emphatically with what Drs. Savage and Down had said about the probable syphilitic origin of those cases which begin with spinal symptoms, but we seem to have as a result, in cases of general paralysis occurring in patients with a history of constitutional syphilis, that the disease is modified to a greater or less extent by a greater tendency to local paralysis than in ordinary cases.

Dr. Nichols said in the large number of cases of general paralysis which he had treated, some two-thirds, he thought, had had syphilis. He had really doubted whether syphilis was an essential cause of general paralysis of the insane. It seemed to him that those cases which he had not been able to trace to a syphilitic origin ran their course more regularly than those in which he could, and he had never been able to benefit a patient who had not had syphilis by any anti-syphilitic treatment, and he had retarded the progress of the case in many instances in which he knew that the patient had had syphilis. It had appeared to him that in some way the degeneration of the brain did take on a syphilitic character, although it was accompanied undoubtedly by gross lesions that were common to other forms of brain-degeneration. He might add that he had supposed that excessive venery, excessive intellectual labor, and loss of sleep were the most efficient causes of general paralysis of the insane, and it seemed to him that they would cause it independently of syphilis.

Dr. Spitzka was obliged, in some particulars, to differ very materially from the conclusions of the distinguished superintendent of the Bethlehem Asylum. It was a new suggestion to him that all cases of general paralysis of the insane where spinal troubles, such as locomotor ataxy, precede the mental disturbance are syphilitic in their origin. One constantly growing evil seen in all large capitals was the habit of imperfect coitus indulged in for the prevention of conception. This has a most deleterious effect upon the spinal apparatus. Another was the vicious habit indulged in by those who are losing sexual power. These certainly were causes of locomotor ataxy. The doctor thought that, notwithstanding the objections made yesterday and to-day, we were justified in adopting the term syphilitic dementia. We are shown, in insane hospitals, cases of alcoholic dementia and cases of puerperal insanity.

Now, can you explain the characteristic symptoms of puerperal insanity? It is known in the peculiar combination of symptoms as a whole. Syphilitic dementia differs from ordinary paralytic dementia, or paretic dementia. He had seen hemorrhages in brains, but not from those places in which they were usually found in cases of status epilepticus. Wendel in his monograph has pointed out many of the peculiarities by which we are able to differentiate cases of syphilitic dementia from ordinary cases of general paralysis of the insane, that there are changes found in ordinary cases of general paralysis that are not seen in cases of syphilitic dementia. Dr. Spitzka then enumerated several differences which he found in post-mortems between these two classes of cases. In the matter of nomenclature, he said, we often strain at a gnat and swallow a camel. He could not see why this distinctive term should not be adopted. He believed wine, women, and worry the most potent factors in causing general paresis.

Dr. Hughes asked if anyone present had made post-mortem examination of general paralytics who had died during remissions of the disease, particularly in cases where the patient had suffered from his first attack of insanity and had died during the first remission.

Dr. Brush said he had seen just such a case—a patient who had died of phthisis during the first remission of the disease. The lesions usually found in general paralysis of the insane were found in this case. Dr. Brush was not sure but that the phthisis had acted in this case in bringing about the remission in much the same way as in the case mentioned by Dr. Savage, where the carbuncle had developed between his patient's shoulders.

Dr. Hurd believed that we had all seen cases of general paralysis of unmistakable syphilitic origin. He would ask Dr. Savage if he believed any benefit would ensue in these cases from anti-syphilitic treatment.

Dr. Savage in reply cited the case of a patient who had suffered from paresis of a syphilitic origin, and who, after being put upon anti-syphilitic treatment, enjoyed a remission after a fortnight. He believed this a fair specimen of the results to be found in these cases. Certainly if these cases are not cured, it seems to be the consensus of opinion that they are relieved. He believed that we have reached the high tide of syphilitic pathology, and that it was now time to mark a shore-line. Dr. Savage did not like to have too definite lines drawn in the nomenclature of paralysis. Since we know comparatively little of the relationship between syphilitic dementia and syphilitic general paralysis, we had better not be too definite.

T. E. McGarr, M.D., Utica, N. Y.

GENERAL MEETING.

Friday, September 9th—Fifth Day.

The Congress was called to order punctually at 10 A.M., by The President.

The Assistant Secretary, Dr. W. B. Atkinson, of Philadelphia, made some announcements concerning excursions and receptions, after which the

Secretary-General, Dr. Hamilton, reported that the committee appointed on the time and place for holding

THE TENTH INTERNATIONAL MEDICAL CONGRESS

had recommended Berlin, Germany, as the place, and the year 1890 as the time.

The report was unanimously adopted.

Dr. Hamilton also reported resolutions adopted by the Section in Military and Naval Surgery and Medicine, the purport of which was a recommendation of

UNIFORMITY OF THE REPORTS OF SICK AND WOUNDED IN ALL THE ARMIES OF THE WORLD.

Dr. Hamilton further reported, as having been adopted by the Section in Public and International Hygiene, the following preambles and resolution:

Whereas, The whole community has been shocked by the almost daily occurrence of terrible accidents on many of the railroads, causing considerable loss of life, and by the habitual neglect of the most elementary sanitary laws;

Whereas, As this Section considers itself in a degree the guardian of public health; be it

Resolved, That the attention of this Ninth International Medical Congress be respectfully called to this most important question, and that it be requested to use its influence to obtain the necessary reforms.

The following were reported from the same section on *Thursday:*

After the reading by Dr. Domingo Freire, of Rio Janeiro, representative in the Congress of the Brazilian Government, of a paper entitled "Vaccination with the Attenuated Culture of the Microbe of Yellow Fever," with demonstration of the microbe under the microscope, the following preambles and resolutions were adopted by the Section:

Whereas, Inoculation against yellow fever, if it prove successful after further examination, is calculated to benefit the human race throughout the world; and,

Whereas, The facts presented by the experiments of Dr. Domingo Freire afford a reasonable assurance of its protective influence in Rio Janeiro; therefore,

Resolved, That this Section recommends the co-operative investigation of the results obtained by yellow-fever inoculations as a protective against that disease, and that adequate appropriations by the governments represented in this Congress be made for that purpose.

Resolved, That this action be communicated forthwith for consideration in the general session of the Congress.

The President then called upon Dr. Charles D. C. Phillips, of London, England, to occupy the chair during the delivery of the general address by

G. Fielding Blandford, M.D. Oxon., F.R.C.P., London, late Lecturer on Mental Diseases at St. George's Hospital, London, England, on

THE TREATMENT OF RECENT CASES OF INSANITY IN ASYLUMS AND IN PRIVATE HOUSES.

The inquiry was limited to the treatment of recent insanity only, without reference to the care and maintenance of the chronic insane. Recent insanity in very many cases is a curable disorder. What mode of treatment, then, will afford the best prospect of recovery? Will the latter take place only under asylum supervision, or is there a fair chance of curing the sufferer in a house taken for the purpose, or the house of a medical man? For the great majority of patients asylum treatment is the only available method, but there is a certain proportion of insane persons whom it is important to treat, if it be possible, outside of an asylum, to save them from the stigma of having been the inmates of one, as this may seriously damage their future prospects and position. Among females some may be of high rank, whose friends shrink from the publicity of certificates and asylum surroundings; some may be young girls at the outset of life; others young mothers whom and whose children it is desirable to save from the reminiscence of an asylum. Among men there are not a few to whom confinement in an asylum will certainly bring a loss of employment tantamount to ruin. And a young man's future career may be marred by the same fact. It is, therefore, of importance to consider what mental disorders are likely to be transitory and capable of being treated in an ordinary house, or slight and free from danger to the patient and those about him, so that he may be able to live in such a house, or move from place to place under the charge of suitable companions.

The most transitory of all mental disorders are attacks of maniacal excitement, varying from undue elation and hilarity to very acute mania. The most frequent cases are those caused by drink, varying from ordinary delirium tremens to other forms of insanity seen more especially in women. Very similar forms occur without any history of drink, in persons prone by inheritance to nerve-disturbance. They arise after a sudden shock of bad, or even good, news, or great fatigue, or other exhausting cause, and last a few hours, days, or weeks, the subsidence being often as rapid as the onset. The prognosis as regards recovery is often easy, the doubt being as to duration, and this will be solved by proper treatment.

Patients who are not actively excited or unduly elated, but depressed and melancholic, must be considered from a different point of view. They are more manageable, at any rate in the less acute forms, but the disorder is more tedious, and treatment will have to continue for months rather than weeks or days. But many recover without asylum treatment, many without the aid of a specialist. As the commencement of this depression is almost always slow and insidious, treatment outside an asylum is likely to be adopted at first, so that there is an opportunity of considering how far such treatment is answering or likely to answer. The first objection to be urged against the keeping of a melancholic patient in a private house is the danger of suicide. That an ordinary house, with unguarded windows, staircases, and fireplaces, offers more facilities for suicide than an asylum is certain. But asylums do not afford absolute protection, as our commissioners' reports abundantly testify. Nothing will effectually prevent suicide but the unceasing vigilance of good attendants, and this, in many cases, can be applied as well out of as in an asylum. One symptom which often necessitates removal to an asylum is obstinate refusal of food. When this is determined, and forcible feeding requires the aid of several assistants, it can hardly be carried out in a private house. Another reason why an asylum may be preferred is, that in an ordinary house or family the intense egoism so characteristic of melancholia is fostered rather than removed by the concentration of the attention of all upon the patient and his delusions. In an asylum, especially a large one, he becomes a unit in the number of those treated, and this of itself is often highly beneficial. There is one more variety of insanity which can often be treated out of an asylum. This is acute primary *dementia*, or *stupor*, as it is sometimes called. These patients, though often very lost and idiotic, are seldom dangerous. With plenty of food, air, and exercise, they will get well in a private house, and as they are almost all young persons, it is an advantage that they should escape the asylum reputation.

For the treatment of all patients in private houses one thing is absolutely requisite, viz., funds. Unless proper medical supervision, proper attendants, and proper quarters can be provided and paid for, to an asylum the sufferer should go. Friends are often willing to make a sacrifice, and profess they will pay anything. But this may mean a scanty and poverty-stricken supply of what is necessary, the funds become exhausted before recovery takes place, and then an asylum is necessary, and money is wasted which could hardly be spared. Where means are slender and the duration of the illness doubtful, it is better to send the patient to an asylum at once, and save the money for the convalescent stage. Treatment in a patient's own house is rarely successful, therefore the alternatives are an asylum, or a house adapted to the requirements of the case.

At the close of the address, which was listened to with marked attention, Dr. A. Cordes, of Geneva, Switzerland, moved a vote of thanks to Dr. Blandford for his able and interesting address, which was seconded by Dr. P. H. Kretzschmar, of Brooklyn, N. Y., and then unanimously adopted.

The Congress then adjourned to meet at 9.30 A. M. on Saturday.

SECTION IN GENERAL MEDICINE.

Friday, September 9th—Fifth Day—Morning Session.

Dr. George E. Stubbs, of Philadelphia, Pa., read a paper entitled

RATIONAL TREATMENT OF DISEASES OF THE RESPIRATORY APPARATUS.

He made an elaborate and somewhat extended review of the subject of phthisis. Dust inhaled into the lungs

was a great exciting cause of phthisis. In treating this disease he was partial to counter-irritation with moisture and heat. For this purpose he used flannel wrung out in hot mustard-water, applying this around the chest and putting a dry layer of flannel over this.

Dr. Thomas Hay, of Philadelphia, thought counter-irritation invaluable. He paints the whole exterior of the chest with iodine. He gives large doses of whiskey.

Dr. Eye, of Reading, Pa., read a paper on

A NEW METHOD OF TREATING PHTHISIS.

He does not believe in the cure of phthisis unless it can be demonstrated by the microscope. Whether the bacillus tuberculosis is, in itself, the cause of phthisis, makes no difference so long as we know it to be the invariable accompaniment of this disease. To the white of one egg is added six to eight ounces of water; this mixture is put away in a bottle for five or six days, until the mixture has the odor of rotten egg. From one-half to two ounces of this fluid are placed in an atomizer and deeply inhaled during twenty-four hours. Under this treatment the expectoration becomes thinner and of less quantity, the microscopic examination of the sputa shows a less number of the bacilli, and finally none at all. The experiments attempting to prove that the inhalations of the bacterium termo would exterminate the bacillus tuberculosis have proved a failure. While it is impossible to speak definitely upon the *modus operandi* of this solution, Dr. Eye is confident in regard to the favorable clinical results. He suggests also that, among the fifteen or twenty varieties of bacteria contained in the egg solution, there are probably some which have a fatal antagonistic action upon the bacillus of phthisis. He stops the treatment when the sputa no longer contain the bacilli.

Dr. Eye was asked what he thought of the sulphuretted-hydrogen treatment, to which he replied that it relieved, but did not cure, phthisis.

Sir James Grant, of Canada, read a paper on

DIPHTHERIA.

Diphtheria is of two varieties—the simple and the malignant. We must look upon this disease as a blood-poison. He has used mustard-baths at the beginning of the attack, containing one ounce of mustard to an ordinary bath-tub of water, after which the patient is wrapped in blankets and diaphoresis encouraged. He uses light treatment, iron internally and applied to the pharynx. Nourishment should be encouraged.

We must be very careful about letting the patient move about suddenly, on account of the danger of paralysis of the heart. He must be kept long in the reclining position.

As to the malignant type of the disease, he had never seen but one epidemic, and that about twenty years ago. He knew of no remedies for this form of disease.

It was interesting to note that when there is a large snowfall, and consequent dryness of the atmosphere, diphtheria is less prevalent, and *vice versa*. Moisture in the atmosphere has a predisposing influence. Cases usually do better inland than at the seashore.

Dr. Thomas Hay, of Philadelphia, moved that the thanks of the Section be extended to Sir James for his valuable paper.

Dr. John A. Ouchterlony, of Louisville, Ky., remarked that he was exceedingly grateful to Sir James, especially for the valuable suggestion of diverting the poison to the surface and eliminating it through the perspiration; it was an idea which he had never heard or thought of before.

Dr. A. B. Palmer, of Ann Arbor, Mich., said that he brought the system early under a free perspiration and salivation by means of jaborandi, taking into account, of course, the condition of the heart. He had used counter-irritation, with a similar idea to that of Sir James, in spinal meningitis.

Sir James Grant replied that he had never used jaborandi. Mustard had the advantage of being well known and handy.

Afternoon Session.

Dr. Ouchterlony read a report of the committee appointed to investigate Director Körösi's paper, read on the second day of the Congress, entitled

THE PREVENTIVE POWER OF VACCINATION.

The report reviewed the original paper, which it confirmed in terms highly complimentary to the author.

Dr. A. B. Arnold, the President, of Baltimore, Md., requested Dr. T. B. Lester, of Kansas City, Mo., to occupy the chair. He then read a paper on

DILATED AND FATTY HEART.

He called attention to the facts that degeneration often takes place secondary to cardiac hypertrophy; that in fatty heart and aortic regurgitation we are liable to sudden death, and also that the symptoms of depression in fatty degeneration are due to cerebral anæmia. He made some extended remarks, stating that digitalis should not be used in fatty degeneration of the heart.

Dr. George E. Fell, F.R.M.S., of Buffalo, N. Y., read a paper on

FORCED ARTIFICIAL RESPIRATION IN OPIUM-POISONING, ITS POSSIBILITIES, AND THE APPARATUS BEST ADAPTED TO PRODUCE IT.

In one of the latest extensive works, we find that artificial respiration has a wider range of application than might at first be supposed. It has been used in drowning, strangling, occlusion of the air-passages, hemorrhage, and poisoning from anæsthetics and the various alkaloids. Those methods depending upon the movement of the limbs and body for their success have been usually supplemented with pressure by the physician. In the physiological laboratories experiments are performed, in which the trachea is opened to supply the air for respiration by means of bellows. The insertion of laryngeal tubes aiding in artificial respiration is worthy of consideration.

I have applied the term *forced respiration* to those cases in which the trachea is opened, to distinguish it from the ordinary artificial respiration. After extended inquiries, I have never heard of a case in which forced respiration has been used upon the human subject in opium-poisoning. On July 23, 1887, I was called to see a severe case of opium-poisoning, which, after the ordinary course of treatment, I finally gave up to die. Dr. F. R. Campbell was summoned to the case, at which time we found the respirations only one per minute: the pulse was still to be detected at the wrist. Atropine was at this time administered hypodermically, which soon resulted in a dilatation of the pupils.

Having frequently performed the operation of forced respiration on animals, I suggested the advisability of trying this upon our patient, to which Dr. Campbell acquiesced. The apparatus which I possessed for this purpose was immediately sent for. The operation of laryngotomy was made, the tube inserted, and forced respiration produced.

The pulse soon became stronger and more regular, and in twenty to thirty minutes the respirations themselves began. In three hours the respirations had increased from one to twenty per minute. In twenty-four hours they again went down to six per minute. It was also interesting to notice that after being resuscitated he was taken with an attack of delirium tremens, in which he was maniacal, but from which he soon recovered. He had been drinking very heavily before taking the opiate. There was no injury of the lung-tissue. The original instrument was shown, as well as the improvements made adapting it for use on the human subject.

Dr. Brainard, of Los Angeles, Cal., objects to this method, owing to the danger of the operation. He thought Sylvester's method sufficient, if sufficiently prolonged, and if we used the precaution to pull forward the tongue. The artificial method should be continued faithfully for at least six to nine hours.

Dr. Fell replied that in his case the artificial respiration was kept up until the patient seemed to be getting worse all the while.

Dr. Enterkin, of Ohio, had tried successfully forced respiration in opium-poisoning, by passing an ordinary piece of tubing in through the larynx, and attaching to the external opening an ordinary pair of bellows. The connection had, of course, to be broken with each expiration. John Woodman, M.D., New York.

SECTION IN SURGERY.

Friday, September 9th — Fifth Day — Morning Session.

Dr. George Assaky, of Bucharest, Roumania, read a paper on

IODOL IN SURGERY.

The conclusions arrived at were: (1) Wounds unite under l'iodol by first intention. This union, however, being the result of various and complex conditions attending operation, it is not possible to attribute to l'iodol alone the absence of suppuration and inflammatory conditions. In wounds which gape and suppurate l'iodol is an excellent antiseptic. It rapidly retards suppuration, renders it inodorous, reduces the frequency of dressing, and considerably hastens cicatrization. In ulcerating or gangrenous wounds l'iodol aids in resisting the destructive process, and changes the wound, after a variable time, to a healthy, granulating condition. This action of l'iodol extends itself to hard chancres. In case of soft chancres the result is variable. Sometimes it transforms them into a simple wound with brief delay; at others it is insufficient for this purpose, and it becomes necessary to employ in addition, locally, antiseptic lotions. The same is true with reference to open venereal bubos of the groin.

The powdered l'iodol has this advantage over iodoform, that it is free from odor and is not toxic in its effects.

(2) Doses of l'iodol of from 0.40 centigrammes to 2.0 grammes, daily, produce no functional trouble, even if continued a long time.

These doses give marvellous results in tertiary syphilis and in scrofulous affections. In the secondary stage of syphilis, taken internally, it rapidly destroys the syphilitic manifestations. L'iodol seems to aid the general nutrition and increase strength and flesh. It is indicated in all cases of specific malnutrition.

L'iodol is an antipyretic. In acute infectious diseases, such as erysipelas, etc., it causes a rapid fall of temperature.

Dr. Milton J. Roberts, of New York, read a paper on

A NEW METHOD OF OPERATING ON BONE BY MEANS OF THE ELECTRIC OSTEOTOME.

The speaker presented an elaborate apparatus for this purpose, of most ingenious mechanism. One member remarked that he feared such a display would make the patients feel rather nervous, if seen by them.

The osteotome consisted proper of a hollow cylindrical handle, protruding from which was the shaft of the instrument, at the end of which was a small wheel with teeth like an ordinary finger-saw; the base of the handle was connected with the electric batteries by means of the covered wires usually used in all electric batteries; anterior to the handle were "cut offs," which could be worked by the forefinger and thumb, disconnecting the current in an instant, and checking the revolutions of the saw-wheel just as quickly; according to the diameter of the bone, different-sized saws were adjusted. In connection with this was a set of drills for drilling into any part of a diseased bone and removing the sequestrum or dead tissues in the bony cavity, the cavity being illuminated by a small electric light thrust in at different stages of the operation in order to secure removal of all carious bone. The femur was exhibited, the head of which had been drilled in this manner, the drill-opening into the bone being three-eighths of an inch in diameter, while the entire inside portion had been removed by the drill.

The question was raised as to the cost of such an apparatus being beyond or more than the surgeon would care to invest unless making a specialty of such diseases, and one gentleman affirmed that he could perform all the work which this instrument did with the regular dental drill, and that he had done it on several occasions, borrowing the drill from a neighboring dentist.

Dr. Close, of Illinois, thought the chief advantage of the apparatus was that the operator does not necessarily require skilled assistance, as the current was controlled by the hand in which the instrument was held, while the left hand was at liberty. He had been in the habit of using at times the band-wheel engine for such purposes, but found it too slow; in order to cut bone the saw must revolve quickly in such an apparatus.

Dr. Roberts, in conclusion, said that he had tried the dental engine many times and found the revolutions too slow, and it was for that reason he had set to work in order to secure the best possible method of removing bone in such cases; when the wheel revolves slowly the bone-tissue is torn; had it been satisfactory, he would not have spent the time and money in bringing forward a new instrument. In operating, the periosteum is not lifted or removed, but cut through with the bone. The speaker also exhibited some instruments for measurement, which would record the exact size of the bone to be removed in cases of deformities, etc.

Dr. George E. Post, of Beirût, Syria, read a paper on

CALCULUS IN SYRIA.

The writer remarked that it would almost seem to be produced from climatic causes, as it was such a prevalent malady there. In Palestine in almost every village these cases are extremely numerous both in young and old; in one day four patients came to him from a single village. When an operation is performed, the stone is generally found to be larger than is found in European countries, owing to the natives being extremely averse to all surgical operations, and hence procrastinate; a Moslem dislikes an operation extremely. Then, again, there are not many good surgeons there, and they frequently hesitate to perform an operation for stone; besides, too, the people are ignorant and poor. In that region there is a class of men called "stone-cutters," who make it their business to travel and remove stone from the bladder. They carry a bag containing the stones they have removed, and also those bequeathed to them by their ancestors, if in that calling. Their method of operation is as follows: The patient is laid on his back, without the use of anæsthetics, and held by assistants; the stone-cutter inserts two fingers into the rectum and feels for the stone in the bladder; when felt it is pushed toward the neck of the bladder, and then, with the aid of a razor or borrowed scalpel, he cuts down upon the stone through the perineum, and, when reached, the stone is pushed out by the fingers in the rectum.

The writer quoted one of his cases, in which five stones were removed, two from the bladder and three from the perineal tissue. Another case was more curious than that; the patient had been operated on in infancy by the method described, and a fistulous opening still existed. In that country they are in the habit of eating grapes with skin, seed, and pulp; the fistulous opening connect-

ing the rectum with the urethra had secreted grape-seeds, these forming the nucleus for the stone formation. There were sixty-four stones removed from the fistulous tract and bladder, ranging from the size of a grape-seed to a nut; a portion of one stone was embedded in the prostate, and with a short neck the larger portion was embedded in the bladder.

Another case of the same character, but with a stone much larger in size (weighing six ounces), in which a portion was in the bladder and a portion in the prostate, was removed, and not the slightest disturbance of the system ensued, although the stone was of such large size. In another instance the speaker removed a stone weighing twelve ounces; it was four inches long and two inches wide.

The largest number of calculi he had ever removed from one patient was two hundred, of various sizes, but eleven of them weighed six ounces each. The patient died from double pneumonia three days after. The speaker stated that he had operated in 250 cases of stone in the bladder. The mortality was 10 in 176 cases. One hundred and six of the cases (250) were in children ten years of age and under. He had performed 44 lithotrities, 8 of which died. One patient, a man seventy years of age, came under the writer's care from whom he removed three stones from the urethra—one from the membranous portion, one three inches from the meatus, and one from just inside the meatus—the largest was the size of a bean. Going from one extreme to the other, he cited the case of a child, not quite two years of age, from whom the writer had removed a stone the size of a bean.

Dr. J. A. S. Grant (Bey), of Egypt, remarked that calculus is very common there also. A friend of his, Dr. Zacharol, had made careful and scientific examinations of the various calculi, and almost invariably found the nucleus to be the egg of Bilharzia hæmatobia, and which, he suggested, would account for the stone.

A patient came to the speaker's office one morning with his scrotum extremely inflamed, and about the size of a child's head. The man—a native—while sitting near the railroad track had been struck on the scrotum by a bottle thrown from the hands of a soldier in a train that was passing; the blow had laid open the scrotum. The speaker removed the stone, which weighed fourteen ounces. This was the largest he had ever removed, and was taken away in three pieces.

Dr. R. T. Morris, of New York, asked which species of Bilharzia was found, and also in how many cases the blood-worms were found.

Dr. Grant replied that Bilharzia hæmatobia was in almost every case examined by Dr. Zacharol.

Dr. Post remarked he hardly thought Bilharzia could be a cause, as, while Bilharzia was very rare in Syria, calculi were very common.

Dr. Oscar J. Coskery, of Baltimore, Md., read a paper on

AN UNCOMMON CASE OF FRACTURE, WITH DISLOCATION OF THE TARSUS AND METATARSUS.

The patient, a male, was run over by a steam-car, the right leg being crushed, compelling amputation, and the left foot cut, the before-mentioned dislocation occurring as mentioned. Reduction was impossible, and the patient died nine hours after the accident. At the autopsy it was found that three of the metatarsal bones were completely luxated, the scaphoid projecting up, presenting the appearance very much of such bone in a case of strong pes equinus, while the posterior portion of the os calcis had been crushed and the astragalus bruised.

Dr. N. Senn, of Milwaukee, Wis., read a paper on

ELASTIC CONSTRICTION OF THE NECK, WITH EXCLUSION OF THE TRACHEA, AS A MEANS OF CONTROLLING HEMORRHAGE IN OPERATIONS ON THE HEAD.

He called attention to the fact that where we desired a bloodless operation there were more blood-vessels than in any other part of the body. He thought, however, this hemorrhage could be overcome by the following method, which he had practised on dogs, namely—cutting down on the trachea, separating it from the surrounding tissues, and then passing a strong rubber band behind it, the ends passing backward, the vessels of the neck could be constricted by tightly securing the ends of the rubber band, while respiration could be carried on. One dog, upon which he had operated, retained the bandage for two hours, and is now as well as ever. Another one, where it was retained still longer, had been put under the table, and afterward, when about to be thrown out, it was noticed the heart pulsated, but respiration had ceased. The band was released and artificial respiration practised, when the animal speedily recovered.

Dr. Carnochan, of New York, presented a specimen of

DOUBLE DISLOCATION OF THE HIP-JOINT.

He remarked that previous to 1820 this condition was unknown, but in 1826 Dupuytren first brought it to the notice of the profession. The speaker stated there were various theories as to the causation of this condition, among which were carelessness of the accoucheur, movement of the fœtus in utero, etc; the question arises, also, as to whether it is really a dislocation or a malformation.

Dr. R. T. Morris, of New York, stated that he did not think that it could be caused by careless handling of the physician, as in the northern part of Germany it was quite common, and they certainly had skilled physicians there. He thought it might be due to arrest of development.

Dr. Post drew attention to the two classes of cases, one of which seemed to be rachitic; but he had seen it occur in healthy infants with a difference in length of limbs. A few weeks since he saw a case in which the head of the bone was in the thyroid foramen; the speaker could only account for it that the child moved in utero.

Dr. Link, of Indianapolis, Ind., read a paper on

ALCOHOL AS AN ANÆSTHETIC.

The speaker had used it in over a hundred cases and never had a fatal result, while the anæsthesia was complete. The whiskey was given in two-ounce doses, every two to five minutes, until a pint to a pint and a half had been taken and the patient became stupefied. Then about two drachms of chloroform were placed in the cone, and a few respirations would put him to sleep; the operation could then be carried out. The speaker's reasons for using this method was that in cases of shock there is depression; the alcohol increases the heart's action, while the chloroform, which is a depressant, administered as stated secures the equilibrium of the heart's action.

E. Develin, M.D., New York.

SECTION IN MILITARY AND NAVAL SURGERY AND MEDICINE.

Friday, September 9th—Fifth Day—Morning Session.

AMPUTATION FOR INJURY OF LIVING PARTS NEVER NECESSARY.

A paper upon this subject was read by Dr. Elisha H. Gregory, of St. Louis, Mo. The author mainly described improved methods of coaptating deep structures, and the prevention of wound accidents and complications. He advises that, if by peculiarity of the injury the main channels are cut off, the surgeon should wait for collateral circulation, because the injury is not general.

The second paper was

THE SUPERIORITY OF THE BAVARIAN PLASTER-OF-PARIS SPLINTS FOR GUN-SHOT AND OTHER FRACTURES OF THE LIMBS,

by Dr. James H. Gregory, of Omaha, Neb., and was read by the author, who related his experience and observation

during four years of service as surgeon during the War of the Rebellion. Instances were given in which the spica bandage and other appliances had caused gangrene.

The history of the Bavarian plaster-of-Paris splint was briefly given, after which the writer related his experience in its use, and the proper mode of its application.

Then followed a paper by RICHARD FRANCIS TOBIN, M.K.Q.C.P. Ireland, of Dublin, entitled,

SOME REMARKS UPON THE KIND OF DRESSING MOST AVAILABLE FOR GUN-SHOT FRACTURE OF THE LOWER LIMBS ON THE FIELD IN CONNECTION WITH TRANSPORTATION.

This paper, owing to the absence of its author, was read in abstract by his compatriot, DR. JEFFREY A. MARSTON.

It had reference chiefly to fractures of the upper third of the femur, and to the desirability, in treating such cases, of fixing in an immovable position, not only the injured member but also the opposite limb and the trunk. The appliances that, in the opinion of the writer, best fulfil these indications were described.

DR. J. R. SMITH, U. S. A., opened the discussion with the assertion that the permanent immobilization of fractured limbs upon the field of battle is impracticable.

The injured limb should be rendered immobile temporarily by a common splint, and by being fastened to the other limb, if the leg is involved, or to the body, if the arm be the seat of the injury. In the United States Army all these modes and materials had been tried, and a large number of surgeons have about concluded that the silicate bandage is the neatest, lightest, and strongest dressing for hospital use; the speaker had known patients thus treated to travel from Philadelphia to Maine.

DR. R. B. BONTECOU, of Troy, N. Y., preferred the silicate of soda or potassa as a primary dressing for fractures of the lower extremities, with a view to transportation; it is cheap, hardens quickly, is lighter than plaster of Paris, and can be carried in the field in tin cans of a capacity of one or two litres with a large mouth and screw-cap cover. When used it should be of the density of ordinary sirup.

PRESENTATION TO THE PRESIDENT.

DR. JEFFREY A. MARSTON moved that the President temporarily vacate the chair and that Dr. William H. Lloyd, of the Royal Navy, be installed therein for the transaction of special business.

The motion being unanimously carried,

DR. ELI A. WOOD, of Pittsburg, in a well-expressed speech, presented to the President, Dr. Henry H. Smith, of Philadelphia, in behalf of the members of the Section in Military and Naval Medicine and Surgery, a beautiful vase of agate, and submitted the following resolutions:

Whereas, In consideration of the very extraordinary labors of Henry Hollingsworth Smith, M.D., LL.D., in organizing the Section in Military and Naval Medicine and Surgery, accompanied by great efficiency in presiding over its sessions, it is hereby

Resolved, That Dr. Henry Hollingsworth Smith has pre-eminent claims upon the members of this Section for his judicious administration of its business meetings, and the hearty thanks of the Section are hereby extended to him, with a high appreciation of his useful work in connection with the Ninth International Congress.

Resolved, That a Committee of Drs. J. R. Smith, J. A. Marston, and Ch. D. Phillips be requested to communicate this action to Dr. Smith.

The resolutions were seconded by DR. MARSTON in a brief address emphasizing the high estimate placed upon Dr. Smith by the visitors from abroad, and the cordial appreciation of his personal attentions.

DR. W. H. LLOYD also expressed his heartfelt participation in the recognition of the President's valuable services.

DR. SMITH, in reply, gave utterance to his profound sense of gratitude to the friends who had presented the beautiful present, and to the Section, whose appreciation was prized as an indication that his efforts in honor of the profession and the credit of this country had not been unavailing.

The President, resuming the chair, announced the conclusion of the business of the morning session.

AFTERNOON SESSION.

The proceedings were opened by DR. E. GRISWOLD, of Sharon, Pa., who read a paper entitled

WHAT CONDITIONS ON THE FIELD JUSTIFY AMPUTATIONS IN GUN-SHOT WOUNDS?

The author claimed that amputation on the field of battle cannot always be done, although the established rule of surgery, as well as the opinion of the surgeon, may demand it in many cases in which it is not done. The exigencies of war often separate the surgeon from his equipments and deprive him of the means of action, or he may be overworked and unable to attend to his duty.

The surgery of to-day and of the future makes it necessary for military surgeons to be supplied with means by which asepsis can be practised upon the field in the treatment of wounds, and this can be done and made practical wherever an adequate supply of water is attainable, if a rapid method of filtration and purification is available.

The possibilities of antiseptic surgery are already largely developed, and the military surgeon of the future must know what is to be expected in the way of conservatism; and when his patient, having a severe gun-shot wound in one of his extremities, is found to be clearly beyond the reach of conservatism, he is not only justified in amputating in the field, but it is his bounden duty to do so.

DR. BONTECOU said he would practise conservative surgery when there are arteries to nourish the limb and veins to carry the blood back from the injured member to the heart.

DR. E. A. WOOD alluded to other elements, such as shock, which must be taken into consideration in determining whether amputation be or be not required, and in some instances of probable deformity resulting, with consequent uselessness of the limb, the part should be excised.

DR. COLLINS, of Pennsylvania, thought many cases that would otherwise recover died of the wear and tear incident to the transportation.

DR. H. H. BIEDLER, of Baltimore, Md., adverted to certain operations for grave injuries having terminated fatally after amputation, from the operation itself, and without the complication of shock.

DR. GRISWOLD closed the discussion by saying that he had noticed that shock, in injuries of the knee-joint, seemed to be more serious than in those of the hip-joint.

When the injury is such that amputation is clearly indicated, it should be done early; still, even in bad cases, conservative surgery was available, and an attempt should always be made to save the limb.

The paper presented by DR. CHARLES SMART, United States Army, was, at the request of the author, read by title, and referred to the Committee on Publication.

THE PRESIDENT announced that the business before the Section was concluded, and with a few appropriate remarks declared the Section adjourned.

R. LORINI, M.D., Washington, D. C.

SECTION IN OBSTETRICS.

FRIDAY, SEPTEMBER 9TH—FIFTH DAY—MORNING SESSION.

The Committee appointed to formulate resolutions in regard to

UNIFORMITY IN OBSTETRICAL NOMENCLATURE,

submitted its report, which, after an animated discussion, was unanimously accepted, the only dissentient being Dr. Martin, of Berlin, who was not present but had left a message stating that he thought the matter should not be settled by an American Congress, but should wait three years and be accepted or not by a congress meeting in the Old World.

REPORT AS ACCEPTED.

A. It is desirable to try to attain to uniformity in obstetrical nomenclature.

B. It is possible to arrive at uniformity of expression in regard to: 1, The Pelvic Diameters; 2, The Diameters of the Fœtal Head; 3, The Presentations of the Fœtus; 4, The Positions of the Fœtus; 5, The Stages of Labor; 6, The Factors of Labor.

C. The following definitions and designations are worthy of general adoption by obstetric teachers and authors:

I. PELVIC BRIM DIAMETERS.—1. Antero-posterior: (1) Between the middle of the sacral promontory and the point in the upper border of the symphysis pubis crossed by the *linea terminalis* = *Diameter Conjugata vera*, Cv. (2) Between the middle of the promontory of the sacrum and the lower border of the symphysis pubis = *Diameter Conjugata diagonalis*, Cd.

2. Transverse: Between the most distant points in the right and left ileo-pectineal lines = *Diameter Transversa*, T.

3. First Oblique: Between right sacro-iliac synchondrosis and left pectineal eminence = *Diameter Diagonalis Dextra*, D. D.

4. Second Oblique: Between left sacro-iliac synchondrosis and right pectineal eminence = *Diameter Diagonalis Læva*, D. L.

II. FŒTAL HEAD DIAMETERS.—1. From the tip of the occipital bone to the centre of the lower margin of the chin = *Diameter Occipito-Mentalis*, O. M.

2. From the occipital protuberance to the root of the nose = *Diameter Occipito-Frontalis*, O. F.

3. From the point of union of the neck and occiput to the centre of the anterior fontanelle = *Diameter sub-Occipito-Bregmatica*, s. O. B.

4. Between the two parietal protuberances = *Diameter Bi-Parietalis*, Bi-T.

5. Between the two lower extremities of the coronal suture = *Diameter Bi-Temporalis*, Bi-T.

III. PRESENTATION OF THE FŒTUS.—The *presenting part* is the part which is touched by the finger through the vaginal canal, or which, during labor, is bounded by the girdle of resistance.

The *occiput* is the portion of the head lying behind the posterior fontanelle.

The *sinciput* is the portion of the head lying in front of the *bregma* (or anterior fontanelle).

The *vertex* is the portion of the head lying between the fontanelles and extending laterally to the parietal protuberances.

Three groups of presentations are to be recognized, two of which have the long axis of the fœtus in correspondence with the long axis of the uterus, while in the third the long axis of the fœtus is more oblique or transverse to the uterine axis.

1. Longitudinal: (1) Cephalic, including—vertex and its modifications; face and its modifications; (2) pelvic, including—breech; feet.

2. Transverse or trunk, including shoulder, or arm and other rarer presentations.

IV. POSITIONS OF THE FŒTUS.—The positions of the fœtus are best named topographically, according as the denominator looks—first, to the left or the right side, and second, anteriorly or posteriorly. When initial letters are employed it is desirable to use the initials of the Latin words.

In the case of Vertex positions we have:

Left Occipito-Anterior = *Occipito-Læva-Anterior*, O. L. A.

Left Occipito-Posterior = *Occipito-Læva-Posterior*, O. L. P.

Right Occipito-Posterior = *Occipito-Dextra-Posterior*, O. D. P.

Right Occipito-Anterior = *Occipito-Dextra-Anterior*, O. D. A.

The Face positions are:

Right Mento-Posterior = *Mento-Dextra-Posterior*, M. D. P.

Right Mento-Anterior = *Mento-Dextra-Anterior*, M. D. A.

Left Mento-Anterior = *Mento-Læva-Anterior*, M. L. A.

Left Mento-Posterior = *Mento-Læva-Posterior*, M. L. P.

The Pelvic positions are:

Left Sacro-Anterior = *Sacro-Læva-Anterior*, S. L. A.

Left Sacro-Posterior = *Sacro-Læva-Posterior*, S. L. P.

Right Sacro-Posterior = *Sacro-Dextra-Posterior*, S. D. P.

Right Sacro-Anterior = *Sacro-Dextra-Anterior*, S. D. A.

The Shoulder presentations are (left and right side of the *mother*):

Left Scapula-Anterior = *Scapula-Læva-Anterior*, Sc. L. A.

Left Scapula-Posterior = *Scapula-Læva-Posterior*, Sc. L. P.

Right Scapula-Posterior = *Scapula-Dextra-Posterior*, Sc. D. P.

Right Scapula-Anterior = *Scapula-Dextra-Anterior*, Sc. D. A.

V. THE STAGES OF LABOR.—Labor is divisible into three stages: (1) First stage—from the commencement of regular pains till complete dilatation of the os externum = *Stage of Effacement and Dilatation.* (2) Second stage—from dilatation of os externum till complete extrusion of child = *Stage of Expulsion.* (3) Third stage—from expulsion of child to complete extrusion of placenta and membranes = *Stage of the After-birth.*

VI. THE FACTORS OF LABOR ARE—(1) The Powers. (2) The Passages. (3) The Passengers.

A. F. A. KING, M.D.
WILLIAM T. LUSK, M.D.
A. R. SIMPSON, M.D.

DR. R. S. STRINGER, of Florida, presented a paper on

A RATIONAL METHOD OF RELIEVING ASPHYXIA NEONATORUM,

which, in the absence of the author, was read by title.

DR. IRA E. OATMAN, of San Francisco, Cal., read a paper on the

TREATMENT OF PUERPERAL ECLAMPSIA.

After giving a sketch of the disease and the usual methods of treatment, he recommended, when the convulsions occurred before labor, anæsthesia and clearance of bowels and rectum, together with as rapid delivery as was compatible with the safety of the patient. When the convulsions occurred after delivery and were accompanied by high, nervous, and vascular tension, nothing was so safe, speedy, and reliable as veratrum viride. This he gave in the dose of ℥vj. by mouth, or ℥x. by rectum, repeated every fifteen minutes until the convulsions ceased.

Should the veratrum cause excessive depression an immediate and certain antidote was found in alcohol. It was better to give the veratrum in excessive doses than to risk the continuance of the convulsions, for the brandy or whiskey to counteract its effect were always present, and the veratrum certainly exhibited a remedial action not otherwise attainable. The puerperal period was to be treated as usual, together with treatment of any pathological condition present. He found the veratrum equally efficient in the convulsions of children and in hystero-epilepsy.

Dr. Alexander Simpson, of Edinburgh, Scotland, thought any suggestion that would enable us to control eclampsia of extreme value. He would like to hear opinions regarding veratrum; he had used it once twenty years ago, and had not felt inclined to try it again.

Dr. G. Lane Taneyhill, of Baltimore, Md., advocated strongly the use of veratria in eclampsia, and said that fifty per cent. of his cases had, in the last twenty years, been treated by it, he giving ten drops of the tincture hypodermatically every hour of convulsive action, and always keeping another hypodermic syringe with brandy to sustain the heart should the pulse go below forty-two. He was led to this practice by observing its use by Latimer in a case which he could control but temporarily by chloroform. He had not lost one case of eclampsia since using veratria; it enabled him to hold the engine (the heart) in check as an engineer with the air-brake, and was not as dangerous a medicine as was generally supposed. It produced the same effect as bleeding, save that no blood was lost to weaken the patient afterward.

Dr. Duncan C. MacCallum, of Montreal, Canada, had fourteen cases; all recovered. He used chloral, chloroform, potassium bromide, bleeding, morphia hypodermatically, and cleaned out the bowels by stimulating enemata. There was no routine treatment; each case was to be treated on its own merits.

Dr. Pierce, of Ohio, thought it foolish to try to map out any one line of treatment for eclampsia; each case must be rationally treated.

Dr. Lawrence, of Bristol, England, believed in as early delivery as possible, and the use of chloral. In plethora, bleeding was sometimes useful. It was difficult to lay down definite treatment.

Dr. Jones, of Danville, Ill., said that veratrum was an active purgative, and a loaded colon was an active agent in causing epileptiform convulsions. He took charge of his patients beforehand, kept their bowels regular, used chloroform in labor when any nervous symptoms appeared, and saw no cases of eclampsia.

Dr. A. F. A. King, of Washington, D. C., had never used veratria in eclampsia, but had suggested its use twenty years ago theoretically (*New York Medical Journal*, October, 1865), to lessen arterial hyperæmia of the nerve-centres, by reducing the force of the heart. He then, and more recently (in the *American Journal of Obstetrics*, March and April, 1887), considered, and still considers, eclampsia to be caused chiefly (and in addition to uræmic poisoning) by abnormal pressure of the gravid womb upon the aorta and its branches, and vena cava and its branches. He believes this abnormal pressure to be chiefly due to premature descent of the lower uterine segment and fœtal head *below the brim into the pelvic cavity*, especially in primiparæ, two or three months before full term.

In transverse presentations, whether in multiparæ or primiparæ, eclampsia does not occur. The head of the child ought not to sink below the pelvic brim before labor—in fact, such *descent* is the *second* stage in the mechanism of *labor*. Yet recent authorities affirm that it is usual, and therefore normal, in primiparæ. This he denies. He maintains that the normal posture of the fœtus during pregnancy, before labor begins, is transverse or oblique; a head-presentation is abnormal until the sinking of the womb just before delivery, when it changes in order that labor may take place. To remove the cause of and prevent eclampsia, we should, by posture and manipulation, lift the prematurely descended head out of the pelvis, and put it above the brim in one of the iliac fossæ, where it normally belongs, and where it would have remained but for corsets, dress, coitus, and other displacing influences.

Dr. W. W. Jaggard, of Chicago, Ill., said: 1. Eclampsia is a symptom of renal insufficiency, renal inadequacy, to use a term of Sir Andrew Clarke's, the result of functional or organic disease. The arguments of Dr. A. F. A. King were entirely inconclusive. 2. The cause of the convulsions was cerebral anæmia, the result of vaso-motor spasm, caused by irritation of the vaso-motor centre, by excrementitious matter retained in the blood. 3. The indication for treatment was absolute continued narcosis. He used chloroform, potassium bromide, chloral, morphine. Veratrum viride, according to the researches of Wood and Behrens, of Philadelphia, causes vaso-motor dilatation, and the woman is literally "bled into her own veins." At the same time, when this remedy is employed a hypodermic syringe filled with brandy must be ready. Pilocarpin is unreliable, causing cardiac depression, and aiding in œdema pulmonum when no diaphoretic action is effected. Professor Fordyce Barker has frequently called attention to this fact.

Dr. Oatman said that he had seen large doses of as much as a drachm of the fluid extract of veratrum taken by mistake and recovered from without treatment.

Afternoon Session.

Dr. H. O. Marcy, of Boston, Mass., read an elaborate paper on the

histology and pathology of reproduction.

The studies offered were based upon the conviction that the profession owes to the late Professor Ercolari, of Bologna, the establishment of new and simple truths which are fundamental and of the first importance. Comparative studies teach that there is a unity of type in placental development. The writer endeavored to show that immediately after conception a destructive process affects the inner surface of the uterus; in some animals and in women this process is limited to the epithelium, while in other animals, as in the rodents, the destruction extends to the entire submucous connective-tissue layer.

This destruction is essential, since it facilitates the setting up of neo-formative changes, from which will result the maternal portion of the placenta. This process consists in the formation of new vessels, which are distinguished from the vessels of the unimpregnated uterus in that both the artery and vein consist of only a simple endothelial wall, and that from the external surface of this is elaborated a layer of special cells not separable from the wall of the vessel. These are the so-called decidual or placental cells.

The relation established between those two factors of new formation is what is known as placental development. The manner in which this relation is established gives rise to the different forms of the mammalian placenta.

Dr. Alexander Simpson, of Edinburgh, spoke of the value of the paper and sketched the development of the placenta from the lowest type, where the fœtal and maternal surfaces were simply laid together, and were separated at parturition, to the complicated interdigitation in the higher animals, and the highest type as found in the human female, where, at the time of delivery, the maternal as well as fœtal portions came away together, leaving beneath it only the basal portion of the uterine mucous membrane.

Dr. E. Paul Sale, of Aberdeen, Miss., read a paper on the

management of pregnancy, with reference to the prevention of post-partum hemorrhage,

in which he strongly insisted upon the value of prophylaxis, undertaken months before delivery, during which

time the patient should be under the supervision of the accoucheur. Some of the predisposing causes and their treatment are as follows:

1. Hæmophilia, abnormal tenuity of the walls of the capillaries — Use stimulating oils, as turpentine or oleum origanum. Matico, liquid extract, also good. Ergot and allied drugs no value.

2. Anæmia, from various causes — Fluid extract stylothansis, cimicifuga racemosa, salix nigra, etc. Faradization of the abdominal muscles for ten minutes daily.

3. Atonic debility, from rapid childbearing — Exercise, tonics, quinine, strychnia, iron, fresh air.

4. Laceration of cervix, cancer, fibroma—Let alone, except before third month.

5. Intemperance—Moral measures (what success?).

6. Heart disease—Gelseminum.

7. Plethora—Dietetics, salines.

Dr. H. B. Hemenway, of Kalamazoo, Mich., had not been able to diagnose post-partum hemorrhage many months before labor. He asked what was the relation of late ligature of the cord to post-partum hemorrhage.

He strongly suspected that it tended to prevent such an occurrence, and his explanation was as follows: There is no direct connection between the maternal blood-vessels and the placenta; if the cord is ligated late, or if only the fœtal portion was ligated, blood flows from the placenta. The cord is normally attached near the centre of the placenta; if, then, blood is extracted, the placenta must shrink and the edge will first become detached. If blood is not extracted from the placenta, it is more rigid, and as the uterus contracts the centre is likely to be first detached. A sac is thus formed which fills with the maternal blood, and the mouths of the uterine vessels do not firmly close. When the placenta is delivered, this accumulated blood rushes out and the maternal vessels again bleed.

Dr. W. W. Jaggard, of Chicago, called attention to the following propositions:

1. Late ligature of the cord is always indicated in the interest of the child—when not contra-indicated in the concrete case. The researches of Budin have demonstrated that when the cord is ligatured when it ceases to pulsate the child receives seventy-five grammes of blood—lost when the pulsating cord is tied. The relation of late ligature of the cord to the prevention of post-partum hemorrhage, to which the gentleman from Michigan has called attention, is of great interest, if it be a fact.

2. The best preventive of post-partum hemorrhage is to secure retraction of the uterus, by keeping the hand on the fundus uteri from the moment the child begins to pass through the vulvar outlet until the muscular fibres have rearranged themselves—about one hour after expulsion of the placenta.

Kucher, in his admirable book, has called attention to friction over the fundus twice daily during the first two days of the puerperium. This is the practice in Vienna. There is little danger of dislodgement of a clot in the uterine sinuses, or interruption of the process of puerperal thrombosis, by this procedure. It is also an excellent prophylactic against resorption of septic matter.

Dr. George Wheeler Jones, of Danville, Ill., read a paper on

DYSTOCIA FROM RIGIDITY OF THE CERVIX AND ITS MANAGEMENT.

After a consideration of the various conditions which might cause rigidity of the cervix, he spoke of the most important—spasmodic contraction. Here opium was most valuable, together with chloroform and Barnes' dilators, if quick dilatation was necessary. Sitz baths, warm vaginal douches, delivery in a warm room, morphia hypodermatically, quinine where there was malaria, salicine in rheumatic cases, and electricity were all useful. He would never use chloral, as it was dangerous to mother and child. He then detailed some original investigations into the medicinal action of Gassypii radix, delphinium, and ipecacuanha.

Dr. A. F. A. King, of Washington, D. C., called attention to the fact that the thinning of the uterine segment and the obliteration of the cervical canal, conditions which led to the rigidity of the cervix, were abnormalities. When the uterus and child maintained during pregnancy their normal lateral obliquity, the canal of the cervix from the external to the internal os will remain unobliterated until full term, which is the normal condition both for primiparæ and multiparæ. Under the same normal circumstances the great thinning of the lower uterine segment, the tearing of the decidual mucous membrane, the "formation of a new cervical canal," and the other tissue-changes observed by Bandl, will be absent *during pregnancy*. They are abnormal. They may nevertheless occur *during labor* from *abnormal* mechanical obstruction to delivery. Dr. King also objected to the use of chloral.

Dr. Brooks H. Wells, of New York, did not agree with Dr. Jones concerning the great danger to the unborn child from the use of chloral. In about one hundred cases out of between six and seven hundred which he had had under his charge, or had witnessed, it had been used both as an anæsthetic, where the first stage had been unusually painful, and in spasmodic rigidity of the cervix, and in no case had he seen any harm accrue to mother or child, but only the most gratifying results. He always used the precautionary measure mentioned by Dr. Jaggard, viz., to keep himself informed of the condition of the uterus by a hand placed over the fundus, slight rotary friction overcoming any possible tendency to relaxation, and had never had any serious post-partum bleeding, either with or without the use of chloral. Its administration might, in full doses, blunt the pains somewhat. He was accustomed to administer the drug in ten to fifteen grain doses, by mouth or rectum, until this result was attained—usually from two to four doses. He considered morphia and the hot douche important agents in treating the class of cases mentioned.

A paper by Dr. John H. Wilson, of Chicago, Ill., entitled "Puerperal Uræmic Amaurosis," was read by title.

The Section then adjourned, after passing a vote of thanks to Professor Simpson for the felicitous and able manner in which he had presided.

Brooks H. Wells, New York.

SECTION IN DISEASES OF CHILDREN.

Friday, September 9th—Fifth Day.

Dr. A. B. Judson, of New York, Vice-President of the Section, called the meeting to order. He said that it might be called the first meeting of the Subsection of Orthopædic Surgery, the embryo of what may in the future be a mature section.

A paper was read by Mr. William E. Balkwill, of London, entitled

THE TREATMENT OF CONGENITAL CLUB-FOOT, DEMONSTRATED BY THE EXHIBITION OF APPARATUS.

The writer limited himself to the consideration of talipes equino-varus. He believed that in the majority of cases tenotomy will be required. The question of an early or late operation is to be answered by considering the general condition of the child rather than the nature of the deformity, as a severe case may be as thoroughly and permanently reduced, if circumstances make a delay desirable, a few months after birth as if the operation was done in the first week. He divides the tibialis posticus, the tibialis anticus, and the plantar fascia, in the order named, and after an interval of three weeks of the diligent use of a flexible splint and bandages, he is ready to proceed with the division of the tendo Achillis. Then, instead of extending fully and at once after tenotomy of the Achillis, and keeping the foot in the new position,

he takes more time, and, in fact, uses the foot as Isaac Walton did his frog—no force, no undue pressure, but careful guidance.

Mr. Balkwill then exhibited a large number of ingenious instruments designed to accomplish complete reduction by the gradual method. Their action was controlled by the pinion-key in some instances, and in others by modifying with suitable wrenches the tractable steel of which they were constructed. He deplored the existence of a strong prejudice among people of all classes against the wearing of "irons." If properly constructed and correctly applied, they should do the work required, not only without pain, but with an increase of comfort, arising from the increased facility which they add to locomotion. He feared that surgeons were largely responsible for the existence of this prejudice, from the fact that it is so much easier to refer the case to an instrument-maker than to give to it the care and painstaking which it requires, and without which success is impossible.

A paper was then read by Dr. Lewis A. Sayre, of New York, entitled

SECTION OF CONTRACTURED TISSUES ESSENTIAL BEFORE MECHANICAL TREATMENT CAN BE EFFECTUAL.

The writer defined his position as follows: A contra*cted* tissue is one that is simply shortened, but which can be elongated by careful, continuous, and judiciously applied traction and manipulation. A contrac*tured* tissue is one which has undergone some change of structure in the fibrillæ of the muscles, and which cannot be elongated or stretched. Distortions or deformities which are the result of contrac*tured* tissue can only be removed by forcible rupture of the same, or by cutting before traction is applied; but similar deformities resulting from simply contracted tissue may frequently be rectified by manipulation and constant traction, properly applied, without section of the tissue. How are we to know whether the tissue is *contracted* or *contractured?* If in any case of club-foot or other deformity from muscular contraction we stretch the shortened parts to their utmost tension by manual force or mechanical aids, and when the parts are thus stretched we suddenly add to the tension by pressing with the thumb or finger on the part thus stretched, or by pinching the stretched tissue between the thumb and finger, and if by either of these acts we produce a *reflex* spasm, or sudden shivering of the whole body, that muscle, tendon, or tissue, thus yielding this *reflex spasm* is *contractured*, and cannot be elongated *without severing* of its fibres. If, on the contrary, when the test is applied as above described, and no *reflex* irritation or muscular spasm is produced, it is evident that the parts are simply *contracted*, and can be further elongated by persistent constant traction and proper manipulation, and therefore do not require divulsion.

To attempt to stretch a contractured tissue causes unnecessary pain, and exposes the patient to the risk of disturbances of the nervous system through long-continued irritation. In all such cases it is infinitely safer to make such division by subcutaneous section than by manual or mechanical force. Treatment is to be completed by massage, friction, active and passive motion, electricity, and such mechanical appliances as may be required in each case. A number of illustrative cases were given.

The Vice-President, Dr. A. B. Judson, of New York, thanked Mr. Balkwill for bringing over the instruments which he had shown, braving the terrors of the New York Custom House in order to add to the interest of the Congress. His view of the subject was that the treatment of congenital club-foot is divided into two stages by the arrival of the time when the child begins to try to stand. Before this time, when the child's weight does not interfere with corrective procedures, the varus should be reduced by whatever means may be at hand—a succession of carved-wood splints, tractable metal splints, adhesive plaster, plaster-of-Paris splints, the artificial muscles; or a combination of these methods, one with another, or with tenotomy, as the case may require. Whatever the plan adopted, by the time the child begins to put his weight on the foot, the varus should be so far reduced that the sole is presented squarely to the ground. Of course, if nothing more be done, the varus would return when walking begins, and would soon be as bad as ever; and what is now required in this, the second stage, is a slight splint extending up the inner side of the foot and leg, and so fitted with buckles and webbing that pressure may be distributed where the steel is directly applied, and concentrated on the outer side of the ankle, where it can be easily borne, because made by webbing-straps. The object of the splint is simply to give the foot a push toward valgus, so that when the child steps the sole presents squarely to the ground, or a little more than squarely. Every foot-fall will then be an impulse in the right direction, applied with the force of the rapidly increasing weight of the body. With tractable metal in the splint, varus may be absolutely reduced, and, if it were desirable, even valgus could be produced.

Mr. Edmund Owen, of London, stated that he was heartily devoted to what he believed was rightly called the American plan. The old plan consisted in dividing first the tendon of the tibialis posticus, and perhaps also that of the flexor longus digitorum, and then in putting the foot up in only a slightly improved position; then, when it was supposed that plastic effusion had connected the divided ends of the tendon, to begin with Scarpa's shoe to correct the inversion. Later on, perhaps weeks afterward, when the inversion had been fairly dealt with, the tendon of Achilles was divided, and in a few days flexion of the foot was started with. Mr. Owen considered that this plan was now, even in England, giving place to the method of dividing all the tendons at one and the same time; and not only that, but bands of fascia and ligament were also divided. He called particular attention to the need of dividing the anterior part of the internal lateral ligament of the ankle-joint, which was much concerned in keeping the front part of the tarsus flexed and inverted on the head of the astragalus. Scarpa's shoe should, together with mechanical spinal supports, be relegated to the limbo of extinct surgical instruments; the introduction of the plaster-of-Paris treatment had rendered them superfluous. There need be no fear of failure of union occurring in the divided tendon after putting the foot at once in the correct position; plastic effusion and blood in the sheath of the tendon quickly prepared the way for an efficient splicing of the tendon.

Mr. Owen could not accept entirely all that Professor Sayre said as to the difference between contractured and contracted tendons; he would not deny its existence in fact, but he was not prepared entirely to accept it. He commended in the highest terms Dr. Sayre's teaching and his practice.

Dr. E. R. Lewis, of Kansas City, Mo., said that if the distinction made by Dr. Sayre was correct, it was a most valuable diagnostic sign. He would try it, and, if successful, would feel amply repaid for his trip to Washington.

Dr. Hingston, of Montreal, Canada, stated that formerly it had been his custom to delay tenotomy till after the period of teething, at least; but he had long ago accepted the dictum of Dr. Sayre, that one is warranted in delaying the operation only till the tenotome can be procured. He had followed this rule with almost invariable satisfaction.

Dr. D. A. K. Steele, of Chicago, advocated the plan of treatment which had been outlined by Mr. Owen. His experience had led him to the adoption of the following rules of practice: (1) Operate as early as the child is brought. (2) Divide all tissues that prevent perfect restoration of the foot. (3) Retain the foot in a correct

position by plaster-of-Paris dressing. (4) Leave the toes out in order to watch the circulation. Antisepsis, of course.

The tripod was then erected, and Dr. Lewis A. Sayre and Dr. Lewis Hall Sayre suspended a patient of Dr. Magruder, of Virginia, and applied

THE PLASTER OF-PARIS DRESSING FOR POTT'S DISEASE.

The following papers were then read by title: "Forcible Correction of Contracted Knee-joint," by Dr. E. H. Bradford, of Boston, Mass.; "The Progress of Orthopedic Surgery," by Mr. Noble Smith, of London; "Anchylosis of the Knee-joint in a Straight Position by Excision, as a Remedy for the Atrophy and Deformity following Acute Poliomyelitis of Childhood," by Dr. Stephen Smith, of New York; "The Treatment of Lateral Curvature of the Spine," by Dr. James Knight, of New York; "The Results of the Treatment of Hip Disease by the so-called American Method," by Dr. A. B. Judson, of New York; "The Diseases of Faulty Habit," by Dr. James F. Goodhart, of London, England; "The Treatment of Strumous Glandular Enlargement of the Neck," by Dr. Martin G. B. Oxley, of Liverpool, England; "The Nature and Antiseptic Treatment of Whooping-cough," by Dr. Moncorvo, of Rio de Janeiro, Brazil; "On Acetonuria in Children," by Dr. Adolph Baginsky, of Berlin, Germany; and "Mediastinal Tumors in Children," by Dr. Oscar Wyss, of Geneva, Switzerland.

The session was closed by a few valedictory sentences by the President, Dr. J. Lewis Smith.

At the close of the session the initiatory steps were taken to form

AN AMERICAN PEDIATRIC ASSOCIATION,

with Dr. J. Lewis Smith, of New York, and Dr. W. D. Booker, of Baltimore, Md., Provisional President and Secretary. A. B. Judson, M.D., New York.

SECTION IN OPHTHALMOLOGY.

Friday, September 9th—Fifth Day—Morning Session.

The Section being called to order, Mr. H. Power presented a new pattern of *ophthalmoscope, folding handle*, for vest-pocket use, which could be carried in a case much like a pair of eyeglasses. A paper was also mentioned as having been sent by Dr. David Prince, of Jacksonville, Ill., "On some Points in the Treatment of Dacryocystitis and Affections of the Nasal Duct," with a new cannula for drainage, which instrument was exhibited to the Section.

Dr. E. Smith, of Detroit, Mich., then read a paper on

THE TREATMENT OF ABSCESSES AND ULCERATIONS OF THE CORNEA WITH JEQUIRITY.

He remarked upon the experience, common to all, of the difficulty in procuring the absorption of pus in the cornea, and noted the existence of the same tendency in all closed abscesses. The best means of arresting suppuration, and of getting rid of the pus when formed, has engaged the attention of the writer, with many others, for years. A paper on the above subject, in the spring of 1883, with another published in October, 1883, gave the result of his observations up to that time. He had since had many cases of ulceration of the cornea speedily relieved, and an astonishing clearing up of the cornea after its use. He believes the remedy affects the proliferation in corneal corpuscles. After explaining his impression of the mode of action of the remedy, he proceeded to describe his manner of using it. He does not use a strong preparation, and aims not to produce a sharp inflammation, as is done in trachoma. He uses a three per cent. solution, or a very minute quantity of the powdered seed. It is applied sparingly, till a mild catarrhal inflammation is set up, characteristic of the remedy, and in some cases there may be slight membrane. The object is to avoid a high degree of reaction. The eye is kept washed out with a two per cent. solution of boric acid, and the result is almost uniformly surprisingly good. The corneal cicatrix is often hardly apparent to anyone but the patient.

Dr. Galezowski, of Paris, France, said that he did not like jequirity. In his observation it had frequently produced ulceration and destruction of the cornea and synechia anterior, and in some cases enucleation had to be made to avoid sympathetic trouble. He thought jequirity exerted a very bad action on the cornea. The modification in Dr. Smith's method is doubtless in the amount of the drug used. Dr. Galezowski thought it a dangerous method.

In intermittent fever he had found ulceration of the cornea, which yielded to the administration of quinine. In another case, lasting for several months, after the extraction of a tooth, cicatrization occurred. The best treatment for corneal abscess and ulcer is the antiseptic method. He applies the powdered iodoform directly to the surface three times a day, under cocaine, and uses the steam douche two or three times a day, ten minutes at a time. When it is not doing well cauterization with a solution of nitrate of silver, twenty-five centigrammes to ten grammes, may be done once or twice every day.

Dr. Richey, of Washington, D. C., wished to know whether scraping the ulcer before applying the remedy had not been found of advantage.

Dr. Smith, in closing, said that Dr. Galezowski had used jequirity in trachoma, in the way described by De Wecker, till he obtained marked diphtheritic membrane. In these cases it was the swelling and chemosis that caused strangulation and loss of cornea. He should hesitate to use jequirity in sthenic cases; it was the asthenic cases requiring stimulation that were suitable for this treatment.

Dr. D. S. Reynolds, of Louisville, Ky., read the next paper, entitled

NECESSITY FOR REFORM IN THE MANNER OF DESIGNATING LENSES.

He said that often the difficulty was more in the defective apparatus than in the methods employed. The method which he employed was to abandon the idea of measuring and denoting lenses by their focal distance, and make the radius of curvature the measure of the lens, having them measured from a unit of ninety degrees, or the quadrant of a circle. The lenses might be graded at intervals of five or ten minutes, and in the higher grades have an interval of fifteen minutes. He gave a description of an instrument of Professor Snellen's for determining the value of a lens. It consists of a stand with upright, on which a horizontal beam carries at one end a lamp, and near it a positive lens of one-sixth. In the centre of the beam is placed a clamp for holding the lens to be tested. On each side of the centre, on the beam, is placed a lens plano-convex one-twelfth. Near the lamp is placed a copper disk, perforated by two lines of minute holes, one line perpendicular and the other horizontal. At the farther end of the beam, working in a graduated brass plate, is a frosted glass disk. Steel tapes pass up through the stand and along the beam, connecting with the frosted disk and the perforated plate. It is easy by this means to note the exact point where the point of light reaches the frosted disk without any red or colored margin, and by revolving the lens on trial in the clamp any irregularity can be easily ascertained.

Dr. Landolt, of Paris, wished to know how the essayist would express in writing the power of the glass by his proposed method. In reply, Dr. Reynolds wrote the prescription for a supposed case on the black-board:

O. D.		O. S.	Bis C.
$+\frac{1}{20}$ c. 90°	⌒ $+\frac{1}{40}$ s.	$+\frac{1}{60}$ c. 75°	⌒ $+\frac{1}{60}$ s.	$2\frac{1}{2}''$

Mr. J. Richardson Cross, of Bristol, England, wanted to know the focal length of the unit of Dr. Reynolds'

system, and received the reply that it would be something less than an inch.

Dr. Landolt suggested that the radius of curvature, while most accurate as a unit of measurement, is not satisfactory, as with the same radius there may be differences in composition and differences in the refractive power. The manufacturers' lenses will tell you that the refracting index of lenses is a variable quantity, and no one can make lenses, even of the same material, that will always have an exactly similar refracting index.

Dr. Burnett, of Washington, D. C., thought we could not get along without a knowledge of the focal distance of the lens. His objections to the proposed change were that Dr. Reynolds' plan lacks simplicity, and that the present method seems to answer the purpose very well and is universally adopted, and that the change would be very difficult to make.

Mr. Cross thought that the proposed plan was based on scientific accuracy. But, as a reformer, the author must not expect to succeed until he can give us a medium which is as accurate as his quadrant. The speaker himself was perfectly content with the accuracy of the metre. Of course it is not quite accurate, but much more so than any other measurement we have. Then, all refraction deals with focal length. Our patients want to see at a certain distance. We fit them with glasses to see to a particular point. Again, contrast the simplicity of the metre with the complicated formula of Dr. Reynolds. It is as bad as going back to the inch-system.

Dr. Allen, of Pittsburg, Pa., was unwilling to return to the old system of numerals in refraction. We deal constantly with distance, and distance is measured on a straight line. He thought the adoption of the method would be a step backward.

Dr. Thompson, of Indianapolis, Ind., thought we could not always make scientific methods practicable. He was well enough satisfied to write in the metric system. There was no certainty in the composition of spectacle-lenses, even in pebbles, of which so much was talked about all over the country, and so few sold.

Dr. E. Jackson, of Philadelphia, Pa., then read a paper on

THE DESIGNATION OF PRISMS BY THE MINIMUM DEVIATION INSTEAD OF BY THE REFRACTION-ANGLE.

The object of the paper was to urge the advisability of extending the same principle to the numbering of prisms that now obtains in relation to lenses. The refracting power of the prism depends upon the substance of which it is composed, and upon the medium in which it is placed. The latter being air, it can be eliminated in practice. The same difference existing in the material of which prisms are made as in that of spherical and other lenses, it follows that prisms cut to the same angle may differ very much in the extent to which the ray is bent in passing through them. For instance, a prism marked 3° may have a refracting power of 1.51° or 2¼°, and yet be the correct one according to the prescription, by our present method of measurement. Among a number of prisms tested, only one set came within sixteen per cent. of the supposed standard. He proposed to take as the basis of measurement the minimum deviation, or the deflection of the ray when it passed through parallel in the prism to the base, or where the angles made with the surface on entering and leaving were the same. The change could be easily made without producing confusion with the present system by marking the number of the new system inside a circle, thus, (2).

Dr. Landolt, of Paris, expressed himself as much interested in the paper. It was exceedingly meritorious, logical, and practical, and he would regard it as an honor to carry out the proposal to support the idea. He moved that the Section take up and support the opinion expressed in the paper.

Dr. Reynolds seconded the motion.

Mr. Power, of London, England, moved that a committee be appointed by the Chair to take charge of the subject, and to report at the next Congress. Carried unanimously.

Dr. G. S. Norton, of New York, read a paper on the

RELATIVE IMPORTANCE OF SMALL DEGREES OF ASTIGMATISM AS A CAUSE OF HEADACHE AND ASTHENOPIA.

He related a number of cases which had occurred to him, where correction of astigmatism of only 0.25 D. caused relief to follow with remarkable rapidity. His conclusion was that 0.25 D. of astigmatism may, and not infrequently does, produce disturbance, which its correction relieves. It most commonly occurs in children and young girls that small degrees occasion disturbance and asthenopia. If the hyperopia is of high degree, it is better to try to correct the trouble with spherical glasses first.

Dr. F. B. Tiffany, of Kansas City, Mo., next read a paper, under the title of

AMETROPIA,

introducing a series of statistical tables based on examination of over two thousand school-children in Kansas City, including three races—white, red, and black. The object of each examination was to ascertain the condition of the eyes, nature of the affection, and endeavor, if possible, to remedy it. The examination took in hypermetropia, astigmatism, and spasm of accommodation, as well as myopia.

The matters of light and ventilation were so well arranged that they might be eliminated as factors in the result. It appeared as if the greater number of ametropes in proportion were in the higher classes, and it might be said that ametropes were more fond of study than emmetropes. Spasm of accommodation developed into myopia. If the eyes were examined each year and corrected carefully, the anomalies would gradually diminish. Hazel eyes are most affected by myopia; blue and gray stronger than hazel, brown, and black. Females have more myopia than males, and Indians are mostly emmetropic.

Dr. Burnett, of Washington, D. C., remarked that he suspected that in the prompt relief spoken of by Dr. Norton the astigmatism was between 0.25 D. and 0.5 D. He found that when one of these cases did so well with 0.25 D., that the total amount was somewhat greater.

Dr. Herbert, of Philadelphia, has been astonished to find how little annoyance is felt in high degrees of ametropia and astigmatism, and how much from slight degrees. He had had to not infrequently prescribe as low as 0.2 D.

Dr. Tilley, of Chicago, remarked on Dr. Tiffany's paper that every new-born child is hypermetropic. Myopia does not generally occur till six or seven years of age.

Dr. Young, of Iowa, remarked that the astigmatic glass determined under atropia was not always accepted. The ciliary muscle did not always readily change its compensatory contraction, and a cure by cylinders was sometimes worse than the disease.

Dr. Dickinson, of New York, related a case of reflex irritation, with nausea, etc., existing three years, which had been promptly relieved by correction of a very low-power cylinder.

Dr. Baldwin, of Montgomery, Ala., wished to state, as to the condition of the negro in regard to refractive troubles, that in over nine hundred cases he had only found an error of refraction in about eight per cent. This seems to bear out the old doctrine that civilization increases eye troubles.

Dr. Calhoun, of Atlanta, Ga., stated that it had been his experience that the negro had very little refractive trouble, and if they have not been to school, none whatever. He had known of but one near-sighted negro up to ten or fifteen years ago. Now myopia is becoming more frequent. They are subject to other eye troubles,

specific affections of the cornea and other parts, but they do not seem to be so serious as in the white, and get well very easily, with almost no treatment at all. Another thing, glaucoma is of extremely uncommon occurrence among them. He had only seen three cases among negroes.

Dr. Burnett, of Washington, D. C., could corroborate what Drs. Baldwin and Calhoun had said concerning the increase of myopia in the negro of late years, and desired also to call attention to the fact that the negro does not squint. He thought that glaucoma occurred in the negro, although, perhaps, not to the same extent.

Dr. Blitz, of Minneapolis, Minn., wished to add his testimony to what had already been said about refractive errors and squint in the negro. He finds disease more easily handled in the negro than in the white.

Dr. Galezowski, of Paris, said that in many cases asthenopia was caused by small degrees of astigmatism, but in many others this had not the effect. He instanced the case of a student, an American, who suffered great inconvenience when using his eyes. Professor Hirschberg, of Berlin, found a slight degree of astigmatism, and corrected it, which relieved the patient for two weeks, and then he became worse again. He came to Paris, and under Dr. Galezowski's notice, who suspected that it was not the ametropia that was causing the trouble. Examination disclosed tenderness over the supra-orbital notch, over the right eye, and all around the left eye. He suspected trouble with the teeth, and found one that had been plugged, but was not tender. He had the plug taken out, and found a small piece of rubber crowded up through the top of the tooth. The tooth was extracted, and the patient recovered. These cases are not infrequent. In other cases it may be a slight alteration in the lachrymal puncture. To test the matter, Dr. Galezowsky injects tepid water, and if it enters the nose badly, it is treated by daily injections and dilatation of the canal, not catheterization.

Dr. Reynolds, of Louisville, Ky., remarked upon the difficulty of having the patient wear glasses properly, especially in people who were not in the habit of wearing them. In some cases the distance between the eyes has to be so nicely adjusted that the patient must have a pair for distance a little wider apart, and a pair for near work closer together.

Dr. Gradle, of Chicago, found very few of his cases of asthenopia relieved by weak cylinders.

Dr. Leartus Connor, of Detroit, Mich., did not recollect that he had had occasion to use as little as 0.25 D.

The President referred to his own experience as corroborating the remarks of the previous speakers in relation to errors of refraction in the negro.

Dr. E. Smith, of Detroit, Mich., found a great amount of refractive error among negroes, and said that it was not uncommon for him to operate upon them for strabismus. It may not be so in the pure negro. In his section they are considerably mixed.

Dr. Erwin, of Ohio, stated that as oculist to the Pennsylvania Railroad Company he had found that about twenty-five per cent. of the men employed in the transportation service are astigmatic, and yet not more than twenty per cent. of those referred for special examination have astigmatism. None of the twenty per cent. complained of vision, except referred for spectacles, and only ten per cent. of those so referred required correction of astigmatism to relieve suffering.

Dr. Norton, in closing the discussion, said that he had not advanced the subject as anything new. He agreed with Professor Galezowski that many other causes might produce asthenopia and neuralgic symptoms. As to the exact determination of the amount of astigmatism, he used two sets of radiating lines, one coarser than the other, and when the patient was able to see all the lines in the finer diagram he was quite sure to be accurately corrected.

In rising to adjourn the Section The President, in a few well-chosen words, thanked the members for bearing with him and so cordially supporting his endeavors, and expressed the hope that it had been a season of pleasure and profit to all. There was no doubt about its having been a success.

Mr. Power, of London, England, moved a vote of thanks to the President for his agreeable way of conducting the meetings, and thanked the Section and the profession for the very pleasant time enjoyed.

Dr. Landolt, of Paris, France, wished to warmly support Mr. Power's motion. To the good help of their American brethren, as well as the untiring energy of the President, the success of the meeting was due.

Dr. Galezowski, of Paris, France, also expressed his pleasure and thanks in a few well-chosen words. The Section then adjourned *sine die*.

After adjournment Mr. J. Richardson Cross, of Bristol, England, gave a demonstration of the method of

RETINOSCOPY,

as used by him with Doyne's optometer.

N. J. Hepburn, M.D., New York.

SECTION IN DERMATOLOGY AND SYPHILOGRAPHY.

FRIDAY, SEPTEMBER 9TH—FIFTH DAY.

Dr. A. R. Robinson, of New York, read a paper on

ALOPECIA AREATA, WITH DEMONSTRATION OF DEEP-SEATED MICRO-ORGANISMS.

Believers in the parasitic origin of alopecia have advanced clinical facts to strengthen their theory, while those who believe in its neurotic origin, and they are in the majority, advance other clinical features to substantiate their views; thus the circular nature of the patches, their appearance shortly after injury of the tissues, nerve-shock, neuralgias, etc., and the occasional spontaneous regrowth of hair. On the other hand, the believers in a fungus or micro-organism refer to the well-known tendency of the disease to spread by contiguity of tissue, its occasional occurrence in members of the same family, etc. To prove either case it would be necessary, in the first instance, for the bacteriologists to make cultures, and by inoculation reproduce the disease. In the same way, those who claim a nerve-origin would be forced to show under the microscope changes in the nerve-tissue, or be able to produce a case of alopecia areata by causing an injury of a nerve supplying the scalp. The author carefully and exhaustively reviewed the literature bearing upon the subject of etiology in alopecia, and gave the observations of Ichorst, Thin, Von Lehlen, and others who have observed micro-organisms in this disease. He called especial attention to the manner of origin and spread of the disease, the absence of inflammatory symptoms, the complete falling out of the hair, etc. If the disease depends entirely upon an organism which is so difficult to find, we should not expect so rapid and sudden a falling of the hair. The complete falling of the hair at once is against this theory of a micro-organism, as some hairs would be likely to escape its ravages and remain scattered over the patch. Again, if so abundant as to cause this, they should have been long since easily detected. The fact of broken-off hairs free from the fungus at the seat of fracture, the manner of the fall of the hair, and the condition of these hairs do not permit of a fungus as a cause. Redness in the patch is an exceptional condition, and not to be suspected of being due to a parasite. The loosening and falling out of the hair have been attributed by Dr. Thin to growing organisms. The fibrillation of the hair is the result of atrophy and not of direct action. The hair-root is usually thin and pointed.

Von Schleu discovered organisms especially in the hair-follicles, and mostly in the hairs retaining their root-

sheaths after epilation. We learn, then, from many observers that micro-organisms are pretty constantly present. Cultures, however, fail. Similar organisms are found upon the normal scalp. Cultures when inoculated produce only slight inflammation. If the disease is parasitic parasiticides should cure it, while in fact they are not successful in controlling it. The disease is not contagious in the usual sense of the word. Experiments in inoculation are always negative, but too much stress must not be placed on this failure. The liability of the disease to disappear spontaneously interferes with the accurate observation of the effects of remedies. It may be that the failure of parasitic remedies is due to the disappearance of the organisms before the clinical aspects of the affection really appear, or very soon after the hair has fallen. He has found parasiticides of more benefit when employed early, and they are the most trustworthy means at our command at the present time. Dr. Robinson has been led to believe that the disease does not depend upon a micro-organism to be found upon the surface of the skin or in a hair-follicle, and has been led to look for the cause in deeper parts. To be sure, alopecia has been produced by injury, and neuralgia frequently precedes or accompanies it—but the observations are too few. A general alopecia from shock should have more importance attached to it. Still there are clinical points against the neurotic theory. The author then described the appearances presented by microscopic sections which he had made deep into the tissues, at various stages of the disease. Skin taken from the scalp, on which an alopecia had existed for one week, showed normal epidermis, signs of inflammation in the corium round-cell collection in the sub-papillary layer, cellular infiltration of round-cells blood-vessels dilated, and small arteries containing fibrinous coagulum. The lymph-channels in the corium were enormously dilated and contained also a fibrinous coagulum. The sebaceous and sweat-glands were not affected.

Some hair-shafts showed signs of splitting up and of malnutrition. There was a mild inflammatory condition of the sub-papillary corium, a falling out of the hair, which was replaced by lanugo. In this case the hair grew rapidly again. In a case which had lasted for six months, attributed by the patient to mental disturbances, the same changes were found, but greater ones in the papillary layer. The embryonic cell-collection was marked, and the coagulation distinct. In a case in which the alopecia had existed for several years, causing almost complete baldness, there was found atrophy of all the structures, excepting the vessel-walls. There was some atrophy of the fat-tissues, and only the remains of sebaceous glands were at times found. The hair-follicles showed signs of falling of the hair, there was atrophy of the papillæ, and inflammation, not particularly perifollicular. The inflammatory changes in these cases pointed to this as a direct cause of the loss of hair. In severe cases the secondary disappearance of the sebaceous glands occurs at times and the skin becomes thinner. There is a temporary narrowing of the blood-vessel lumen in all cases. The sudden falling of the hair would be explained by the thickening of the walls and coagula in the vessels supplying the affected area. The inflammatory changes leading to temporary or permanent baldness is a disease of the corium and not of the hair-structures. Alopecia areata is not a hair-disease at all. The author could not consider the disease a trophoneurosis. And the view that it was a vaso-motor disturbance of central origin was not to be entertained ; hence he looked for a local cause and found micro-organisms like those described by Von Lehlen. They were present in the lymph-spaces of the corium and sub-papillary layer, with some in the papillæ, and also deep down in the corium. They consisted of cocci in masses, colonies, and lines, and in rows in the lymph-spaces. Diplococci were frequently seen. In the case of one week's duration micrococci were very abundant.

The question arises : Are they accidental or causative ? A local agency is suggested : The spread of a patch ; the development of new ones. The manner of spreading is cleared up by considering micro-organisms causative when we remember how they travel in the lymph-channels, as in erysipelas. The slight or non-contagiousness is explained by their deep seat, as is also the frequent failure of parasitic remedies. Treatment must be by penetrating remedies, by internal ones. The soil must be rendered unfavorable by building up a run down subject, or the organisms must be killed directly. Remedies advised are sulphur, pyrogallol, mercury, chrysarobin, which latter is quite reliable. Croton-oil and remedies producing inflammation almost always control it.

In the discussion, Dr. Unna said that just as summer changes to winter and back again, so do the views upon the etiology of alopecia first favor the neurotic then the parasitic theory.

He himself might be said to hold both views. One must, however, have his mind directed to the possibility of a parasitic origin when one sees, as he has, a father and daughters in one family simultaneously affected. On the other hand, an alopecia following an injury to the scalp, as from a needle broken off in the tissues, rather favors the opposite view, and one must recognize a neurotic origin for cases of general alopecia following shock, etc. He could only offer his congratulations to Dr. Robinson on the scrupulous original work which he had done and the admirable manner in which he had presented the result of his investigations. The two theories rise side by side, each having points of strength and weakness. He thought it would be a long time before either became the recognized one for all cases of alopecia areata. To prove the parasitic theory, isolation, cultivation, and transmission were necessary.

Dr. Ravogli said he had found small corpuscles resembling micro organisms in the epidermis, around the hairs, and in the hair-follicles and hair-shaft. He related the case of a lady who complained of an itching in a circumscribed spot, shortly after which a spot of alopecia areata occurred at this point. He related the clinical histories of several other cases.

Dr. Knaggs related a case of general alopecia following a severe dental neuralgia. The perchloride of mercury, pilocarpine in large doses, the extraction of the teeth, were without avail. Faradism finally resulted in a cure. After this the patient had marked anæsthesia of the whole body, especially of the scalp. A strong current was necessary to make him feel the application. Afterward he suffered intense agony when the electricity was given, even in weak current.

In other cases he had used twenty per cent. oleate of mercury with benefit.

Dr. Zeisler agreed with Dr. Unna that it would take a long time to bring about a union of the two opinions regarding the cause of alopecia areata. We must admit the presence of micro-organisms when, as now, they are found after careful methods of staining, etc. Each one must form an opinion for himself, and this opinion is apt to be on the side to which the majority of his own cases appear to belong. He related two cases in which the neurotic origin appeared unmistakable. One was in a case of exophthalmic goitre (Basedow's disease) ; the other followed a stroke upon the head.

Dr. H. J. Reynolds said he had favored the neurotic origin, but we cannot question Dr. Robinson's observations. The cause seems to have been shown by him to reside in the deep skin, and the pathology established, but he is not convinced that a neurotic trouble may not give rise to the changes described. It is a question whether the organisms enter from without, or find their way to the locality of the patch from within the body.

He had never seen micro-organisms present. He suggested the use of a galvanic current to aid absorption of parasiticides. This he thought would show whether organisms were the cause of the disease if a cure was hastened.

Dr. Thin said it was evident that we now had a demonstration for the first time of micro-organisms in the deeper tissues of the skin in alopecia. He had come to the conclusion, many years ago, that a blooming fungus about the hair-roots was nothing more than epithelial structures. He had himself described micro-organisms in and around the hair-shafts. After his observations, however, for a time the theory of a trophoneurosis predominated.

Clinically, the patients are healthy and present no cause for attributing the condition to a micro-organism. Since then aniline dyes have come in and Von Sehlen has shown a micro-organism. He wished to refute the idea that micro-organisms are present in all hairs.

If the surface of the scalp be disinfected and the epilating forceps scrupulously clean, none will be found in health. In alopecia they exist in numbers proportionate to the distance from the centre of the patch, few being found at the edges.

He did not think cultivations and reproduction necessary before we could accept the theory. We cannot expect mathematical demonstration in these matters. We accept other organisms as causative. No one doubts the tricophyton, still he is not aware that anyone has succeeded in reproducing ringworm from cultures.

The organism shown resembles the one he saw both in form and size, and he thinks Von Sehlen's organism the same. It is not found in the broken hairs, and he thinks the staining and washing washes out many of the organisms. Examination before staining shows minute bodies which have more or less disappeared after washing.

More or less hairs are swollen and ruptured; why should they be unless a force is exerted from their interior?

Dr. Robinson's arguments appeal to gentlemen whose minds can accept micro-organisms for lupus, tuberculosis, lepra, etc. The theory is gradually gaining ground.

Dr. Robinson, in closing, said he was sorry more notice in the discussion had not been taken of the histological changes. Inoculation, if practised, would lead us wrong if a negative result was obtained.

Cases following injury might be explained by our knowledge of the inoculations in osteo-myelitis, the disease not showing itself until the bone has been injured. The existence of organisms in the lymph-spaces explains the disease to his mind, and he is as much convinced of that as he is that tinea versicolor is a parasitic disease.

SECTION IN LARYNGOLOGY.

Friday, September 9th—Fifth Day—Morning Session.

The session was a short one, and, on account of the absence of the authors, several papers were read by title. The only one read and discussed was upon

the action of the epiglottis in swallowing,

by Carmalt Jones, M.D., of London, England.

The old idea, and perhaps the one which is even now most prevalent, is that the epiglottis acts like a lid hinged to the base of the tongue, and by a simple backward movement covering the larynx and directing the food into the œsophagus. The author does not believe that it has any such simple action as that. There is always a slight regurgitation of food and liquids as they are grasped by the middle and inferior constrictors, which would be apt to lift up the epiglottis and pass beneath it. As a result of personal experiments, he finds that the epiglottis on irritation folds the sides together so as to grasp the upper part of the larynx. When this spasm occurs, one must wait until it relaxes before trying to pass a brush into the larynx, or it will glide over the epiglottis into the œsophagus. He thinks that the backward movement of the tongue in swallowing is, for the most part, theoretical. One can swallow well with the tongue held between the teeth or firmly grasped by the fingers. There is only a slight effort to draw it back. We swallow more through the action of the pharyngeal muscles. The larynx is raised toward the base of the tongue, and the constrictor muscles do much toward closing it. The epiglottis is drawn down by muscular action and moulds itself about the upper part of the larynx instead of acting like a simple lid.

Dr. O'Dwyer, of New York, said that in trying to lift the epiglottis for the introduction of the tube he has found that it is often folded about the larynx so firmly as to require a little force to pass the finger beneath its posterior border and lift it up.

Dr. William Porter, of St. Louis, mentioned a case where he had removed the greater part of the epiglottis, and the patient had but little difficulty in swallowing. He thinks that the epiglottis is only accessary, and that the sphincters have much to do in closing the larynx.

Dr. C. S. Allen, of New York, related the case of a syphilitic patient where the centre of the epiglottis had been destroyed down to its base. On irritation, the long, thin borders, which were left with muscular attachment intact, were closely approximated and formed a fair protection to the larynx.

General discussion followed as to the difference in action under irritation and when simply swallowing.

There being no other papers for the morning session, Dr. E. F. Ingals, of Chicago, explained, by aid of the blackboard, a very practicable method of obtaining an abundant supply of compressed air. He had a large kitchen-boiler placed in the basement and connected with the running water, which had a pressure of thirty or forty pounds. The water entering the bottom of the tank compressed the air in the upper part. As the air was used he would allow the water to run into the waste-pipes and air enter the tank from above, and then turn on the water-pressure again.

Dr. C. Slover Allen, of New York, presented to the Section

a new snare and écraseur.

The advantages demonstrated by using the instrument were shown. It can be used with one hand, even when the greatest power is applied, while the other hand is free for holding the speculum. It is made of steel throughout, so that there is no possibility of its breaking. The ends of the wire pass beneath a small excentric, and are quickly fastened or released by the simple movement of a lever. The angle of the instrument is such that no part of it or of the hand interferes with a clear view of the part operated on. The rings for middle and index fingers are attached to either end of a double lever, crossing the sliding frame and pivoted to it at the centre. The lever carries a ratchet-catch on either side, which fits into ratchet-teeth on the sides of the square rod or frame. The thumb-ring is at the end of this rod. When both finger-rings are pressed upon, the sliding frame is drawn down and held by the ratchets, and the wire loop suddenly contracted upon the tumor. The alternate movement of index and middle fingers causes the advance of the ratchet on one side while the other holds, and the wire being drawn down gives great leverage power that will cause it to cut through dense tissue.

Afternoon Session.

A very interesting paper was read on

the longitudinal tension of the vocal chords, its physiology, and its derangements,

by Dr. C. M. Desvernine, Havana, Cuba.

The paper was the result of a long series of experiments and dissections, showing the isolated action of each separate muscle, and the effect on the vocal chords where different groups acted as co-ordinate factors. It was thoroughly exhaustive in treating the subject, both

in experimenting on the cadaver and the action of the muscles in the normal larynx of a living subject. The paper showed hard work, and good, earnest investigation.

TREATMENT OF CHRONIC STENOSIS OF THE LARYNX AND TRACHEA BY INTUBATION.

Dr. J. O'Dwyer, of New York, first gave a short sketch of his earlier experiments, and passed around specimens of his tubes showing the gradual improvement from the crude round and oval short tubes first used to the perfected ones now used. Specimens were shown of the larynx of children of different ages, with the tube inserted. Two specimens were shown of a healthy larynx and diphtheritic one of same age, showing by sections through them at various points that the diminishing of the calibre was caused, not by the false membrane alone, but by a considerable amount of submucous thickening.

The objection had been made that the calibre of the tubes for children was too small, but it was easy to demonstrate that the calibre of the small tubes was larger in proportion to the size of the trachea than was that in the adult tubes. A complete set of the instruments were shown, and the method of introducing and removing the tubes was demonstrated.

The histories of a series of cases were read where subglottic stenosis was successfully treated after tracheotomy had failed. In the first case he was forced to begin with the smallest child's tube, and gradually increase the size until free breathing-space was produced—in eighteen days. The stenosis was the result of syphilitic contraction, and returned in three months; he used tubes for a month, and then resorted to occasional introduction for a few hours. He then taught her to introduce them herself. When worn for a very long time the metal tube may cause ulceration, which is not the case with rubber. He often found so much pain and irritation during the first few hours after introduction that he had to give a hypodermic of morphia in spite of the previous application of cocaine.

He treated a case where syphilitic ulcers had caused adhesion of the cords and complete closure of glottis. Tracheotomy had been performed. Dr. O'Dwyer forced a passage through with forceps and finger, and then used a tube, but was finally obliged to remove a portion of the cords. Cartilaginous support was absorbed and weakened to such an extent that he could not leave out the tube. The patient disappeared for ten months with the tube still in. When he removed it on her return, he found obstruction by granulation tissue. This was removed, and she has since dispensed with the tube. Some at first have great difficulty in swallowing while the tube is in the larynx, but soon learn how to do it with more comfort. Semi-solids are better than either solids or liquids.

In tracheal contraction and stenosis he would be inclined to open the trachea and lay in a tube with an enlarged portion or shoulder at each end, and then sew up the wound, leaving it there permanently. The trachea is far less sensitive than the larynx.

Dr. Browne, of London, spoke in the highest terms of the grand success that had attended the years of study and patient work of Dr. O'Dwyer, and said that he was commissioned to purchase a complete outfit for his hospital. He was surprised that tubes could be retained in so sensitive an organ.

Dr. O'Dwyer closed the discussion, and exhibited a laryngeal speculum and a snare for removal of membrane and small papillomata from below the vocal cords.

Dr. William Porter, of St. Louis, read a paper in which he narrated three cases of benign tumors of the pharynx. In the second part of the paper he presented a new treatment of cystic goitre by substituting for the usual iodine injection a piece of catgut steeped in iodine, withdrawing it after inflammation had been excited. The patient wore a compress and did not stop work.

Dr. Stockton had used injections of a few drops of pure carbolic with benefit.

The Section then adjourned, after a vote of thanks to its President and officers for its excellent management.

C. Glover Allen, M.D., New York.

SECTION IN DENTAL AND ORAL SURGERY.

Friday, September 9th—Fifth Day—Morning Session.

CLINICS

A very interesting clinic was given by Dr. A. R. Starr, of New York, in capping the exposed pulp of a tooth.

It is only of late years that any progress has been made in treating and protecting an exposed tooth pulp so as to preserve its vitality. The operation caused the patient very little pain, and all those who have had the opportunity to see it agreed that it was a success.

Dr. William J. Younger, of San Francisco, implanted a tooth. Great diversity of opinion was expressed as to the ultimate result of this method of supplying lost teeth.

Dr. R. B. Adair, of Gainesville, Ga., completed the treatment of a case of pyorrhœa alveolaris.

Thirty-two other gentlemen gave clinics on filling teeth and constructing artificial dentures.

Professor F. Busch, of Berlin, Germany, read a paper on

THE COMPARATIVE PATHOLOGY OF THE TEETH, WITH SPECIAL REFERENCE TO THE TUSK OF THE ELEPHANT.

A number of specimens were shown by the doctor to illustrate his paper. At its close he exhibited an instrument for removing the small birth-marks so often found on the face. The instruments have a circular cutting edge ranging in size from one-fourth to half an inch in diameter, and fit into the dental engine. The mode of operation consists in selecting a knife the size of the mark to be removed, placing it upon the spot, and quickly revolving it. It will take only a moment to accomplish this, and the operation is said to be almost painless. The only dressing the doctor applies is dry cotton, which he leaves in position for from six to eight days, at the end of which time the part is perfectly healed.

Discussion of the paper was taken part in by Drs. Wm. H. Atkinson, of New York, and W. C. Barrett, of Buffalo, N. Y.

Dr. E. Andrieu, Paris, France, read a paper on

THE SIXTH-YEAR MOLAR.

The essayist held that the sixth-year molar being in development, eruption, and structure an organ of transmission from the temporary to the permanent set, it should be extracted when the permanent teeth are in position. More room is gained by this procedure, and a longer period of usefulness insured to those remaining.

Dr. L. D. Sheperd, of Boston, Mass., expressed his regret that such sentiments should still be prevailing among the profession. He cited cases from practice where the extraction of these teeth caused not alone loss of valuable masticating surface, but actual irregularity of the ones remaining.

Dr. Paul Dubois, of Paris, France, stated that he wished the Section to note that the ideas expressed in the paper were not carried out by the dentists in France.

Professor Frank Abbott, of New York, could see no difference in structure between the sixth-year molar and the other permanent teeth under the microscope, but a very marked difference was apparent between that and the temporary teeth.

A paper by Dr. Th. David, of Paris, France, on "Aphthous Stomatitis," was read by title.

Dr. J. S. Marshall, of Chicago, Ill., read a paper on

OPERATION FOR THE CURE OF A PERSISTENT NEURALGIA OF BOTH TEMPORO-MAXILLARY ARTICULATIONS, AND REFLECTED PAIN IN THE RIGHT BRACHIAL PLEXUS.

History.—Patient, female, forty-two years of age, was operated on some eight years before for the removal of

an osteo-sarcoma of the right inferior maxilla. Extensive suppuration followed, and the wound did not heal for several months. Considerable cicatricial tissue was formed, and the jaw displaced to a considerable extent. Neuralgia dated from the healing of the wound, and the conclusion arrived at was that the irregular position of the jaw was the cause. An operation for the relief of this condition was performed, and the neuralgia ceased. The doctor described the steps of the operation at great length, but failed to show that it differed from methods generally employed

The following papers were read by title: "Articulation of Artificial Teeth," by Dr. H. L. Cruttenden, of Northfield, Minn.; "Power in Dentistry," by W. St. George Elliot, M.D., of London, England; "Porcelain Filling," by Dr. E. C. Moore, of Detroit, Mich.

Dr. Alton H. Thompson, of Topeka, Kan., read a paper entitled

DOES FUNCTION CONTROL THE EVOLUTION OF STRUCTURE?

Some time since, Dr. C. N. Pierce discussed a subject similar to that at the head of this paper. After noticing the mechanical forces involved in and influencing the evolution of the teeth, he says: "Those cumulative forces are utilized through heredity, and, while so potent in tooth-evolution, exert a similar influence in the development and modification of all other structures and organs. All departments of biology recognize the fact that heredity, adaptation, and growth, being of special importance in the evolution of the organic body, must therefore be regarded as especially formative functions. Adaptation to environment might be called the ancestor of function, as function is of organization. Illustrations of modification of structure in response to function are very numerous in which it is shown how an organ may be completely changed or a mere rudiment be fully developed by the demand for the performance of a function unknown before."

A century ago Lamarck laid down the following laws concerning the development of organic life, which we, with all our accumulated facts, can change but little. In his second law he said that, The production of a new organ in an animal body results from the supervention of a new want continuing to make itself felt, and a new movement which this want gives birth to and encourages. Third law: The development of organs and their force of action are constantly in ratio to the employment of those organs. Fourth law: All that has been acquired, laid down, or changed in the organization of the individual, in the course of this life, is commenced by generation and transmitted to new individuals which proceed from those which have undergone those changes. Altered wants lead to altered habits, which result in the formation of new organs, as well as in the modification and growth of those previously existing.

In our study of the subject we will confine our observations to that field in which we, as dental and oral specialists, are most interested—the teeth.

Everything is made for a purpose, and the purpose must precede the thing made for effecting the purpose. Nature plans her work as deliberately as man plans his actions. The means for accomplishing an end are not the cause of execution, but the effect. The organ is the effect, and function is the cause of structure. As food-selection is the cause of the function, so the function of the acquisition and preparation of food is thus the cause of the masticating apparatus.

If function is the cause and support of structure, if an organ develops or atrophies as it is used or disused, if the impulse of active employment dictates the evolution of parts and tissues in succeeding generations, if organs have been suppressed through disuse or remain in various forms as mere rudiments—their function having passed away—then, indeed, must the teeth of man be tending toward final and inevitable suppression.

If in the future of physical education there shall be found a place for education in the accomplishment of masticating food, then, indeed, may the teeth be improved and developed by exercise, as the muscles and lungs are improved and developed.

Owing to the time for adjournment having arrived, no discussion was had on this paper.

The President congratulated the members on the interest they had shown throughout the session, and hoped great good might come from this Congress, both to the profession and their patients.

A vote of thanks was offered to President L. S. Davis for the exertions he put forth in behalf of the dental section.

A vote of thanks was also offered to President J. Taft and the Executive Committee.

M. C. Gottschaldt, D.D.S., New York.

SECTION IN CLIMATOLOGY.

Friday, September 9th—Fifth Day.

The papers read in the Section were: "The Demographic Effects of introduced Diseases, and especially Leprosy, upon the Hawaiian Races," by Dr. George W. Woods, Surgeon, United States Navy; "The Native Treatment of Disease in Syria," by Professor Thomas W. Kay, Syrian Protestant College, Beirut, Syria; "Demographic Consideration of the Evils of Artificial Methods of preventing Fecundation and of Abortion in Modern Times," by Dr. Thomas M. Dolan, of Halifax, England.

The following is a summary of the paper by Dr. Woods:

Physically and mentally, the Hawaiians were considered superior to all other Polynesian races. They are described as tall, broad-chested, sinewy rather than muscular, with lively, expressive faces, noses slightly flat and often aquiline, mouth and lips large, splendid teeth, and with bodies tattooed. They are intelligent, energetic, kind, simple, and hospitable.

Civilization, represented principally by the Anglo-Saxon race, changed their ancient conditions and ways, and impressed upon this peculiar people their laws, religion, manners, customs, languages, government, opinions, and vices. Climate, soil, and general environment remained the same. Hence the altered conditions in their habits and implanted germs of disease must be looked to for an explanation of the astonishing demographic changes which a century has wrought in the Hawaiian race.

The first effect of the contact with civilization was the inoculation of the race with syphilis, which spread so rapidly that it is now often declared that the great majority of the adult population is contaminated. Then came epidemics of scarlatina, rubeola, pertussis, influenza, and variola, slaughtering thousands; and the native population, which a century ago had been estimated at four hundred thousand, was reduced to forty thousand in 1884. The extraordinary mortality has been attributed to cachectic conditions, venereal disease, poverty, bad food, licentious and vicious indulgences, including ava-drinking, opium-smoking, and excess in intoxicating liquors. Later, leprosy was introduced by the immigration of the Chinese. This disease was spread rapidly by the good-nature, social tastes, and hospitality of the natives; no fear of the disease, eating from the same dish, and passing the pipe or ava-cup from mouth to mouth; cohabiting with infected persons, and promiscuous and compulsory vaccination.

The first case of leprosy in a native was recognized in 1848. From the establishment of the leper asylum, on the island of Molokai, in 1865, to 1885, three thousand and seventy-six lepers were received, showing in a measure the great prevalence of this scourge. For the eradication of leprosy the following measures are recommended: Segregation of the infected, cremation of the dead bodies and, so far as possible, all discharges, morbid and fecal, as well as the clothing and bedding, and proper disinfection of the walls, floors, and utensils used by the living.

Geo. H. Rohé, M.D., Baltimore, Md.

SECTION IN GYNECOLOGY.

FRIDAY, SEPTEMBER 9TH—FIFTH DAY—MORNING SESSION.

DR. HENRY O. MARCY, of Boston, the President of the Section, read a paper on

THE HISTOLOGY AND SURGICAL TREATMENT OF UTERINE MYOMA.

The author presented an interesting array of microphotographs. He showed the multilocular growth, the capsule, the multilobular growth, and the parts at which they lie in juxtaposition; the histological relation of the growth to the uterus; the vascularization; the first injection they were able to make into a fibroid tumor; and discussed the bacilli discovered by Dr. Nelson, of Boston, which he termed bacillus Nelsonii. He showed a number of other cuts, and the specimen of a tumor which he had removed from a woman per vaginam, but which he would not attempt again, on account of its size; exhibited some instruments for the operation of removal of fibroid tumors, of his invention, and discussed the shoemaker's stitch.

Illustrations were thrown on the screen by Drs. Martin, Clark, Nelson, and Hewson.

DR. CALEB R. REED, of Middleport, O., read a paper on

INTER-UTERINE STEM PESSARIES,

in which he favored very much their use for promoting the flow of the menses in cases of local origin, and especially those where there was an ill-developed uterus. He thought that this instrument should come in the list of emmenagogues, and that it should not be condemned with the arrogance which generally accompanies its discussion.

DR. DANIEL T. NELSON, of Chicago, read a paper on

THE TREATMENT OF UTERINE MYOMA BY MEANS OF ERGOT.

The author had gone to much pains to gather statistics from the profession, and made a good argument for this mode of treatment.

A paper by DR. M. D. SPANTON, of Hanley, England, was read by DR. EDOES, of Manchester, England, on the subject of

CYSTITIS IN WOMAN.

Local conditions leading to cystitis in women, among which are enumerated diseased states of the uterine appendages, bands of adhesions dragging upon the bladder, and some of the affections causing obstruction to the passage of the urine, which are often obscure and trivial in themselves, are not infrequently overlooked.

DR. WILLIAM L. REID, of Glasgow, Scotland, read a paper on

THE REMOTE RESULTS OF SHORTENING THE ROUND LIGAMENTS.

He had performed the operation eighteen times. He gave the opinions of the authorities, mostly British, and which were mostly unfavorable to the operation. The discussion which followed this paper was also rather unfavorable to the operation.

AFTERNOON SESSION.

DR. J. H. KELLOGG, of Battle Creek, Mich., read a paper on

ALEXANDER'S OPERATION,

and reported twenty cases. He favored the operation.

DR. W. C. WADE, of Holly, Mich., read a paper on

DISPLACEMENTS OF THE UTERUS,

his paper consisting of thirty-nine terse statements about displacements.

DR. JOSEPH TABER JOHNSTON, of Washington, D. C., read a paper on

THE TREATMENT OF COMMENCING OR THREATENED PERITONITIS BY BRISK PURGATION.

PROFESSOR VULLIETT, of Geneva, Switzerland, had two papers, "Progressive Uterine Dilatation" and "The Buried Suture with Iodized Silk in Vesico-vaginal Fistula." They were read in English by PROFESSOR CORDES, of Geneva.

DR. ADDINELL HEWSON, of Philadelphia, Pa., read a paper on

ABDOMINAL SURGERY.

DR. E. H. TRENHOLME, of Montreal, Canada, read a paper on "Extirpation of the Uterus for Bleeding Myoma."

A number of papers were read by title and the Section adjourned. E. S. MCKEE, Cincinnati, O.

SECTION IN ANATOMY.

FRIDAY, SEPTEMBER 9TH—FIFTH DAY—MORNING SESSION.

DR. J. NEELY RHOADS, of Philadelphia, Pa., read a paper on

THE ANATOMY OF STRICTURE,

in which he reviewed the anatomy of the urethra, and, after comparing the male and female urethra, laid it down as a fact that the former was not a canal of uniform calibre, while the latter was. He also dwelt upon the great sensitiveness of the meatus in both sexes. After describing the different varieties of stricture, he exhibited a full set of his pocket bougies, as made by Snowden, of Philadelphia. This case contained ten 2¾-bulbs, a universal handle, and several different sound- and bougie-points, making a cheap, easily portable, and convenient case, equivalent, by varied combination, to twenty bougies. The principal advantage claimed by the author was that, the bulbous part being in the centre of the sound, the meatus was only dilated up to a certain point, and then the smaller handle prevented further pain, while the bulb, deeper in the urethra, was dilating the stricture.

DR. E. C. SPITZKA, of New York, then read a paper on

THE MESOCEPHALON OF THE TRUE REPTILE,

and one on

THE INTER-CRANIAL NERVE-TRACTS IN THE LIGHT OF ATROPHY-METHODS OF VON GUDDEN.

The observations related to two subjects which were somewhat connected. The first has the significance of the fact that the post-optic lobes varied so much in the animal scale as to have actually been overlooked in some reptiles and amphibia, and to be enormously overgrown in others. He believed to have found this in the relation of these bodies to the auditory nerves. Where these were large the post-optic lobes were large. This observation was confirmatory of the experiments of Baginsky and others.

In the discussion which followed, DR. FRANK BAKER, of Washington, D. C., asked Dr. Spitzka if he could trace the nerve-tract throughout its whole course. He remarked on the importance of the conclusions, and asked as to the course of the atrophied nerve-tracts. The metameric division of the brain and skull could not, he thought, in the present condition of our embryological knowledge, be clearly made out. There could be no doubt that the number of somites was large, and as the differentiation had been very great it was doubtful whether we could properly determine the segmental value of each

nerve. The auditory nerve was probably complex. In conclusion, he asked what Dr. Spitzka had observed as to the separate origin of the cochlear and vestibular branches.

Dr. Augustus C. Bernays, of St. Louis, Mo., in reply to Dr. Spitzka remarked that the sense of hearing was only a modification of the sense of touch, and that the auditory nerve was probably only a sensitive portion of the same spinal nerve of which the facial was the motor portion. He could not see how the nerve of hearing could become attached to the post-optic lobes. He thought that the theory of Dr. Spitzka could not readily be made to agree with this proposition.

Dr. Spitzka, in reply to Dr. Bernays, said that while recognizing the importance of the segmental theory, he did not think it advantageous to engraft biological cranial nerve-anatomy on physiological cranial nerve-anatomy. If the two sets of observations conflicted, he would sacrifice the former.

In answer to Dr. Baker he replied that the difference between the two divisions was recognized; the vestibular branch went to the cerebellum. His observation related only to the cochlear branch.

Dr. A. H. P. Leuf, of Philadelphia, Pa., then read a paper on

THE PROPER METHODS IN THE STUDY OF ANATOMY,

in which he enumerated the many defects in the present mode of teaching anatomy, and, confining his remarks principally to schools in this country, he denounced all schools, with few exceptions, in this respect as bad and unscientific. His list of defects is as follows: (1) The instruction is special as regards certain organs only. (2) It is too general as regards other organs. (3) It is neither the one nor the other as regards still other parts of the body. (4) In generally overlooking the relations of organs to one another in a way that would be very useful to remember. (5) Failure to prepare the student's mind with an incentive to acquire anatomical knowledge before it is imparted. (6) Too little of the philosophy or principles of anatomy, which, if properly taught, would make remembrance easier. (7) The failure to clearly show the connections of anatomy with the other branches of medicine. (8) The great want of good teachers.

To remedy these many defects, he thought it necessary: (1) To teach the special anatomy of *every* organ, distinct from all others. (2) To also give a general idea or outline of each organ. (3) To never fail to do this with every organ or part of the body. (4) To invariably show the true and exact relations of the parts to each other. (5) To always create in the mind of the student a desire for the knowledge to be acquired, by showing its necessity. (6) To show in a natural way, without much artificial mnemonics, how many anatomical principles there are which, if remembered, will do alike for all parts of the body. (7) Thorough instruction as to the relations of anatomical study to the other branches of medicine. (8) To have good teachers and men thoroughly acquainted with the subject.

In the discussion which resulted Dr. Augustus C. Bernays, of St. Louis, Mo., objected strongly to the use of mnemonics or any other artificial means of learning anatomy, and believed that it should be taught from an embryological stand-point alone.

Dr. Frank Baker, of Washington, D. C., was much opposed to the manner of teaching anatomy where only a collection of isolated facts were given. His definition of anatomy was, the science of structure.

Dr. E. C. Spitzka, of New York City, spoke in strong terms against the pernicious methods of teaching anatomy, and thought we should try to raise the standards of our study of anatomy to a level with those in Europe.

Dr. F. W. Langdon, of Cincinnati, O., then read by title a paper on "The Didactic Teaching of Human Anatomy."

AFTERNOON SESSION.

The afternoon session was of short duration, and much time was spent by Drs. F. C. Schaefer, Joseph N. Dickson, and others in discussing the subject of

SKIN-GRAFTING.

The President, Dr. William H. Pancoast, of Philadelphia, Pa., gave a very clear and simple demonstration of the peritoneum and its position in relation to the abdominal organs, by means of different-sized sponges and mosquito-netting. This demonstration is of great assistance in making clear to students the manner in which the peritoneum, a closed sac, surrounds the abdominal viscera. He also stated his theory as to the development of the peritoneum.

After passing a vote of thanks on the part of the Section to the able and efficient President of the Section, Dr. William H. Pancoast, of Philadelphia, for his untiring zeal and interest in the work, the Section adjourned *sine die*. William B. Canfield, Baltimore, Md.

GENERAL MEETING.

SATURDAY, SEPTEMBER 10TH—SIXTH DAY—FINAL SESSION.

The Congress was called to order by The President at 9.30 A.M.

The Secretary-General reported resolutions from the Section in Climatology, concerning the establishing of a bureau of vital statistics; from the Section in Military and Naval Surgery and Medicine, with regard to the prohibition of the use of explosive balls in warfare; and from the Section in Public and International Hygiene, with reference to the necessity of teaching hygiene in the public schools.

Dr. Graily Hewitt, of London, on the part of the foreign members, and after making a few preliminary remarks, in which he conveyed their grateful thanks for the attention which the Congress had received and their high appreciation of the success which had attended its work, offered the following resolution:

Resolved, On the part of the foreign visitors and officers of the Congress, that we desire to convey to the President of the United States our best thanks for his presence at the ceremony of the inauguration of this Congress; that we desire to express to the Executive Committee of the Congress, particularly to Dr. Henry H. Smith, Dr. John B. Hamilton, Dr. A. Y. P. Garnett, Dr. Toner, and Dr. Arnold, our very high appreciation of the efforts they have made for the efficient organization, action, and working of the Congress, which have resulted in so great a success, and that we would convey our warmest thanks to the citizens of Washington for the kind hospitality, both public and private, we have received during our pleasant visit to their beautiful city.

Dr. Martin, of Berlin, spoke in German, and expressed his thanks for the kindness that had been manifested to him and to the other foreign members of the Congress. He had come here with some doubt, but that had been all removed, and its great success would secure for it high rank among the Medical Congresses which had been held.

Dr. E. Landolt, of Paris, France, spoke in French, and said that he had been commissioned to express to the President of the United States their sentiments of profound gratitude. The sanction given by President Cleveland to their Congress had given the greatest charm to their stay in that capital. Returning to their hearths they would preserve the most grateful and respectful remembrance of the President of the Republic, and would say to the whole world that the United States, already so favored, possesses, above everything, a chief who directs them surely in the way of progress and prosperity.

Mr. Edmund Owen, of London, England, seconded the resolution presented by Mr. Hewitt, in a neat speech, which was received with ringing applause. When the history of this grand country is written we trust President Cleveland will have a niche in the temple of fame side by side with those great men, Lincoln and Garfield. When you are in our country we love to hear you say, "We admire your Queen." We can say to you with all truth, we admire, we love your Queen, for her beauty and grace, and in seconding this vote of thanks we simply express a prayer that Mr. President Cleveland and Mrs. Cleveland may long continue in strength and health to preside over a happy, a prosperous, and united country.

The Secretary-General, Dr. John B. Hamilton, made a glowing speech, in which he returned his warmest thanks, especially to the foreign members, who had contributed by their presence, their writings, and their kind words to the success of the Congress.

The President of the Congress, Dr. N. S. Davis, in the name of the medical profession of the United States, thanked the foreign members for their sympathy and their assistance in the work of the Congress, in which representatives from every State in the Union had been present to greet them, and then declared the Ninth International Medical Congress adjourned.

SECTION IN THERAPEUTICS.

Thursday, September 8th—Fourth Day.

A paper on

THE CHEMISTRY AND PHARMACOLOGY OF THE NITRITES AND OF NITRO-GLYCERINE,

by George Armstrong Atkinson, M.B.C.M., was presented, and in the absence of the author was read by Dr. Ralph Stockman, of Edinburgh.

The action of the salts of nitrous acid resembles closely those of the acid which is the essential basis of this group of medicinal agents. Nitrous acid is remarkably unstable; in watery solution of $\frac{1}{3000}$ it may be used for a day or two for experimentation, but it has no advantage over a solution of nitrite of sodium, which possesses identical effects in so far as an acid can be considered identical with one of its salts. Our knowledge of the action of the nitrite group has been chiefly derived from a study of the effects produced by nitrite of amyl. Since here the base (amyl) has a decided action of its own, it is necessary to select a salt in which the base in its combination possesses no well-marked physiological activity. The resemblance between the action of sodium nitrite and amyl nitrite has been pointed out by Gamgee, Lauder Brunton, Hay, Leech, and others. Barth described its highly poisonous qualities. Binz showed that it caused death from general paralysis, especially of the muscular system, no convulsions preceding the fatal issue. Reichert considered it identical in its toxic effects with potassium nitrite. Its effects may be summed up as a paralyzer of muscular tissue, non-striated muscle being affected less quickly than striated. The brain-centres are also affected. The blood becomes of a chocolate color in mammals (methæmoglobin), respirations are slowed, and temperature slightly lowered. Death occurs in frogs from cessation of respiration; after the heart has stopped its movements it is found in full diastole and quite inexcitable.

Post-mortem rigidity comes on early. In rabbits, three grains were a fatal dose in one three pounds in weight. The same appearances were found post mortem. In man, small doses (eight grains) produced great tendency to faintness and considerable acceleration of pulse, with decided lowering of arterial tension. Paralysis of respiration is due to the effect of the nitrite on the muscular system chiefly, but also in part to the effect on the medullary centre. Small doses slightly increase the flow of urine; large always diminish it. Urea and uric acid are almost unaffected. Sugar appears in the urine of rabbits after some hours, if the animal be kept very decidedly under the influence of the drug; but rapidly disappears if the administration of the drug be stopped. The nitrite is largely destroyed in the system, being partly, however, excreted as nitrate, partly, probably, as urea; a portion of it is excreted as nitrite.

The pharmacology of the other nitrite is briefly dismissed. Nitrite of potassium, nitrite of ethyl, nitrite of amyl act in very similar manner to the sodium salt. Nitro-glycerine acts partly as a nitrite, and partly *per se*. In small doses it exerts the nitrite effect as a paralyzer; in large doses it produces convulsions.

Dr. Murrell, of London, England, referred to his discovery of the usefulness of nitrite of amyl in the condition of angina pectoris, and he always advised patients to carry the medicine in a small bottle. The pearls he considered too expensive for use. The tabellæ (Ch. B.) of nitro-glycerine, made with chocolate, he considered dangerous, from their resemblance to confections. He has used nitro-glycerine in one per cent. solution (dose ℥ v.–xv.) in cases of neuralgia of the fifth nerve, surgical shock, asthma (spasmodic and cardiac), and reflex neuroses. He preferred this in epilepsy to the nitrite of sodium, which had been recommended by Dr. Law. In angina, patients can take fifteen minims when they feel the attack coming on; such patients should carry a small bottle with them for immediate use when they feel the attack coming on, otherwise they might perish before the agent could be obtained. He gave an amusing instance of the difficulty of obtaining nitro-glycerine in England at present.

Dr. Upshur, of Richmond, Va., reported a case in which the inhalation of nitrite of amyl, in a patient suffering with heart-failure and puerperal septicæmia, undoubtedly saved life by cautiously continuing the remedy, whenever there was failure of the pulse, for about forty-eight hours, when it was withdrawn and diffusible stimulants substituted.

Dr. Wade, of Holly, Mich., prefers a ten per cent. alcoholic solution of the amyl nitrite, which he uses by inhalation. He regards it as the best form of cardiac stimulant in sudden emergencies.

Dr. Phillips, of London, England, had experienced headache, dizziness, and faintness after taking five minims of a one per cent solution of nitro-glycerine hypodermatically. He had found the tabellæ (each ℥j. of a one per cent. solution) useful in angina pectoris. Patients usually will not tolerate more than three or four of these, but some will require twenty-five or thirty. The effect of sodium nitrite is more prolonged than for the ethereal nitrites, and for this reason he prefers to give it in dyspnœa attending bronchitis.

Dr. Brackett, of Washington, D. C., reported a case of successful treatment of an epileptic by the use of amyl nitrite by inhalation.

Dr. Wade, of Holly, Mich., recommended nitro-glycerine in cases of threatened local asphyxia of brain from embolism or thrombosis; he had had good results.

Dr. Phillips, in answer to a question, said that he would regard fifteen minims of solution of nitro-glycerine, hypodermatically given, as a dangerous dose.

Dr. Murrell thought that there was no advantage to be derived from its hypodermic use, since it acts so quickly when swallowed.

The next paper was read in German,

ON THE POISON OF THE COBRA,

by Dr. Julius Gnezda, of Berlin. The substance from which the experiments were made was brought from India by Dr. Robert Koch. It was obtained by making the cobras strike some shells covered with sheepskin. The poison was afterward dried. It is soluble in water, but not in alcohol or ether; its activity is lost by boiling. It is uniformly poisonous to higher animals. The European hedgehog and the ordinary swine of this country

are popularly believed to enjoy an immunity, but this is explained by mechanical obstacles to absorption in these cases. The poison is contained in an albuminous fluid, but its chemical construction is not as yet settled. It is poisonous when applied to mucous surfaces, without causing blisters.

The effect is very marked when the poison is injected into the circulation. The blood-pressure is at first increased, the blood-corpuscles are changed in their shape, and the spectrum of the blood is characteristic. It was found that death did not occur at once, but after about half an hour, and as the result of failure of respiration, so that the Indian Government was induced to recommend artificial respiration in such cases. At present, no antidote is generally accepted. Since it is not known whether the poison is an alkaloid, a ptomaine, or other body, such a question is at present only a speculation. As it is secreted by salivary glands, it is probably an albuminous body. Permanganate of potash has not been found an efficient antidote.

Dr. Phillips, of London, regarded the paper as an interesting contribution to our knowledge of the characteristics of snake-poison.

Dr. Lewin, of Berlin, could not harmonize the report made of the spectroscopic appearance with the usual characters of the blood-spectrum. The appearance was peculiar, and needed further investigation. With regard to the antidote, it may be acknowledged that there can be no general antidote to counteract the poison after it gets into the system; but if the remedy can be injected *locally* into the wounds, then potassium permanganate and a number of agents having a caustic effect may neutralize or destroy it.

Dr. Woodbury said that in regard to the nature of the poison, Drs. Mitchell and Reichert, of Philadelphia, had conducted a series of experiments which seemed to establish the fact that the snake-poison is not a single substance, but is probably composed of two, one of which is of the nature of a peptone. In the "Life of Francis Buckland," the English naturalist, the incident is given of Mr. Buckland having been inoculated with a very minute portion of the virus, accidentally, under his finger-nail. He shortly afterward suffered with intense pain at the back of his head, faintness, and collapse, from which he recovered with difficulty after taking large doses of ammonia and brandy. He attributed his recovery to the antidotal effects of these agents. We may conclude that when a minute amount has been absorbed ammonia and alcohol are antidotal, but where any considerable amount is received into the circulation the case is hopeless.

Dr. Traill Green said that he had made some experiments with snake-poison, and had been surprised by the quickness of the effects on a rat which had been bitten over the jugular vein. Death was instantaneous where the poison entered the blood directly.

Dr. L. Lewin, of Berlin, read a paper

ON THE MAXIMAL DOSES OF DRUGS.

Of the many difficulties which pharmacotherapy has to strive against, the dosage of medicine is by no means the least. Variation in dose arises (1) from the differences (*a*) between one person and another; (*b*) between single individuals at different times; (*c*) between the intensity of the disease in men suffering with the same affection; (*d*) between diseases in which the same drug is used. (2) From the variability in the activity of the greater part of our remedies.

At the same time it is possible and desirable to establish the usual dose of agents which are active in relatively small quantity, and which readily produce toxic effects when the dose is increased. Two groups of preparations fall under this head: (1) Plants (crude) and plant-products, and their pharmaceutical representatives; and (2) chemical substances such as metalloids, metallic salts, and carbon-compounds.

The first group is almost universally inconstant in its effects, and thus far an international agreement as to their maximal doses has not been possible. The remedies of the second group, on the contrary, are nearly uniform, and the doses beyond which they cannot be given without danger can be determined by physiological experiment; but although the basis for such agreement is tolerably broad, yet the statements given in different pharmacopœias in many cases vary greatly. Such variation can be easily explained in the case of the first group, but becomes incomprehensible in the second.

From the results of his own observation and a comparison of the most of the pharmacopœias which give maximal doses, the author had constructed a table of the ordinary maximal doses of many of the drugs belonging to the second group, which he appended to this communication. Such a list should be added to the pharmacopœias of such countries as have no maximal dosage, for the convenience of the practitioner, who thus would be enabled to prescribe such drugs with confidence even if they should not be generally used in his own country. From this Congress he hoped the influence would go out which would make such an international agreement possible.

Dr. F. Woodbury instanced the varying effect from chloral hydrate, which is sometimes taken safely in large doses, and at other times it proves rapidly fatal, even in doses of ten grains. He inquired if this effect could be due to the coincidence of digestion and the change of the chloral into chloroform by the alkaline bile, as Liebig believed.

Dr. Stockman said that the amount of chloroform liberated from ten or fifteen grains of chloral hydrate would be so small as to be trifling. He thought that it was not decomposed, but that it acted as chloral hydrate. A good deal of dissatisfaction has been felt with chloral on account of its depressing action, and other agents, such as hypnone and urethan, have lately been introduced to take its place.

Dr. H. G. Beyer, U.S.N., said that Mayer had explained the action of chloral hydrate as that of trichloracetic acid; and, in fact, all other halogen derivatives of organic compounds produce their effects by the chlorine which they contain, which is said to be set free whenever these compounds are brought into an acid medium. For instance, the cells of the cerebrum are supposed to react slightly acid during intellectual activity, but when trichloracetate of sodium is injected into the blood, the chemical compound is decomposed, chlorine is set free, and sleep produced, or intellectual torpor, in the same manner as this is done by chlorine hydrate.

Dr. John N. Upshur, of Richmond, Va., read a paper entitled

THE EMMENAGOGUE ACTION OF THE MANGANESE PREPARATIONS.

The usefulness of potassium permanganate when used as a deodorizer and disinfectant is based upon its readiness to part with its oxygen. Its mode of action is not clear, but in small doses internally it acts like iron, improves the general nutrition, and causes an increased and easier flow of blood at the menstrual period. The permanganate of potassium and the oxide of manganese are both used, the latter being more acceptable to the stomach than the former. It is given in gelatine-coated pills (gr. j. to ij. after meals), and to get its full effect it must be given before three successive periods. In amenorrhœa, due to an impoverished and cachectic condition of the blood, oxide of manganese, given in combination with some form of iron, will undoubtedly prove of benefit. It is also useful where the condition is due to defective nervous or vascular supply, when pain is present due to functional disorder; also when *no* obstruction exists, but the endometrium is in a state of chronic congestion, or is affected by inflammation due to obstruction which has been removed; in all cases of vicarious menstruation; in

amenorrhœa of plethora and obesity; *in fine, when the menstrual derangement is due to functional and not mechanical or obstructive cause.* Especially had he found it advantageous in membranous dysmenorrhœa. An interesting case was reported in illustration of the latter class.

Dr. DeWitt Clinton Wade, of Holly, Mich., read a brief communication on a

FORMULA FOR OFFICINAL DILUTE HYDROBROMIC ACID (U. S. P.).

In 1874 he had first made the acid by the reaction of tartaric acid upon potassium bromide; and in 1875 had published a paper recommending its use in therapeutics. It was made officinal in the last revision of the United States Pharmacopœia, but the product is very variable by the official process. He recommends the following for making a standard ten per cent.

SOLUTION OF HYDROBROMIC ACID.

Bromide of potassium, four (*Avoir.*) ounces; tartaric acid, five (*Avoir.*) ounces; water, seven (fluid) ounces. Dissolve the salt in the water and add the acid. When thoroughly mixed set aside in the cold for the precipitation of the acid tartrate of potassium. Decant the supernatant fluid and dilute with sixteen fluid ounces of water. The result is a ten per cent. solution, by weight, of hydrobromic acid.

FRIDAY, SEPTEMBER 9TH—FIFTH DAY.

The following papers were read by title: "On Collinsonia Canadensis," by John V. Shoemaker, A.M., M.D., of Philadelphia; "On Cold as a Remedy in Inflammatory Affections," by Hiram Corson, M.D., of Conshohocken, Pa.; "The Therapeutics of Alcohol in Disease," by E. N. Liell, M.D., of New York City.

Dr. Justus Anndeer, of Munich, read a paper on

RESORCIN AND ITS PREPARATIONS.

In this paper the author briefly gave the result of ten years' experience with pure resorcin. He had found it non-toxic, antiseptic, and possessing many advantages over carbolic acid, being free from odor and non-corrosive to the skin. He had obtained excellent results from it in eczema, in keloid and in parasitic skin-diseases, as well as diseases of mucous membranes. In the form of keratine-coated pills, it can be given for bronchitis, or in combination with castor-oil (one to two per cent.) for diarrhœa and dysentery. For local use it may be combined with cacao-butter as a salve, or it may be made up into a soap of varying strength, from one per cent. up. Failure to obtain satisfactory results from its use may arise from not using a chemically pure resorcin, or from giving it in insufficient doses.

Dr. Lewin said that all are familiar with the writings of the lecturer upon the subject of resorcin. He thought that by devoting exclusive attention to this one member of a group the others might be in danger of having their value slighted. What is the value of thymol? What does resorcin accomplish more than phenol, carbolic acid, and others of this class? He questioned the statement that resorcin is not toxic, since it can in large doses present a condition of cerebral confusion and excitement which closely resembles mania.

Dr. Anndeer replied that the agent was an efficient antiseptic, tasteless, odorless, and in ordinary doses free from toxic effects. He considered it a valuable addition to our therapeutic resources, and superior to phenol and thymol in many respects.

Dr. William Ward, of Washington, presented a paper on

VICARIOUS RESPIRATION SUPERINDUCED IN CERTAIN DISEASES BY ADMINISTRATION OF OXYGEN-YIELDING COMPOUNDS THROUGH THE ALIMENTARY TRACT.

This paper was not finished when the hour of adjournment arrived. The Council of the Section met and passed a vote of thanks to Dr. Traill Green for his ability and affability as President of the Section and for his labors in behalf of the Congress, to the success of which he had so largely contributed.

Frank Woodbury, M.D., Philadelphia.

Progress of Medical Science.

Melanotic Tumors.—Dr. Dieterich has published a statistical comparison of 145 cases of melanotic growth, 114 of which were operated on. Seventy-four of the patients were males, 59 females. In 12 cases the sex is not stated. The age varied very much, as is shown in the following table:

From 0 to 10 years	5
" 11 to 20 "	2
" 21 to 30 "	15
" 31 to 40 "	20
" 41 to 50 "	20
" 51 to 60 "	29
" 61 to 70 "	23
" 71 to 80 "	2
Of unknown age	20

The youngest patient was aged six months, the oldest seventy-five years and nine months. Thus, though no time of life is free of the disease, yet mature age is most exposed to its attacks. As regards etiology, in 37 cases the disease took its beginning from a mole or a wart; in 1 case it was caused by a blister, which produced moist eczema. The growth was on the head in 28 cases, in the neck in 11, on the trunk in 41, on the extremities in 48; in 1 case the site of the disease is not specified. The average duration of the disease to the time of operation was two years and a half; the shortest being a month and the longest twenty years. Of 33 cases operated on there was no record. Of the remaining 81, 53 died; 15 were still living, but the disease had recurred; only 13 remained quite well. The date of recurrence varied from two days to fifteen months. Of these 13 cases 8 were still doubtful, because fifteen months had not yet elapsed since the operation, and recurrence was still to be feared. Thus the number of established cures was reduced to 5. It was proved, however, that operation might produce lasting benefit, one patient having been free from recurrence for twelve years. In cases not subjected to operation, the duration of the disease from the beginning until the death of the patient was, on the average, fifteen months, while in cases that were operated on the corresponding interval was thirty-three months. It would, however, be a mistake to conclude from this that operation prolonged life to that extent, as the cases in which an operation was impossible or inadvisable were, as might be supposed, more severe in themselves, or presented special features of difficulty owing to the disease being situated in important organs, such as the liver. On the whole, operation was advisable, as it offered the only chance, infinitesimal though it was, of saving life.—*Archiv für Klinische Medicin.*

Injections of Carbolized Water in Diarrhœa.—Dr. Illingworth, writing in the *Provincial Medical Journal*, August 1, 1887, says that he has used injections of carbolized water with great success in diarrhœa. He gives one ounce of the one in twenty carbolic lotion, and directs that it shall be added to a teacupful of warm water, to be used as an injection, and retained. The effect is marvellous. He has never yet had to repeat the injection, although he has used it in scores of cases during a recent epidemic of choleraic diarrhœa. The addition of minim or two-minim doses of carbolic acid, to ordinary diarrhœa mixtures, is also of great service in effecting rapid cures of this very prevalent complaint.

Professor Virchow has arranged to accompany Dr. Schliemann on his visit to Egypt next spring.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, September 17, 1887.

THE DISEASES OF THE CEREBRAL ARTERIES.

EVERY large and important organ of the body has a distribution and arrangement of blood-vessels peculiarly adapted to itself. The circulation of the blood in the cranial cavity is especially unique. The four supply vessels—the internal carotids and vertebrals—are so arranged that blood is conveyed in larger amount, and more directly, to the left side. The carotids have a diameter of four millimetres, the vertebrals of three and one-half. The arrangement of the basilar vessels in the form of the circle of Willis, the high importance of the middle cerebral branch as a nutrient channel to motor centres, the absence of anastomoses in the small branches of the pial vessels that pierce the cortex, the arrangement of capillaries and lymphatics, form the chief features of the intra-cranial circulation. Under normal mechanical relations the cerebral arteries are believed by some not to pulsate. They change their calibre, however, and that continually, under various influences. The arterial pressure in the carotids is about one hundred and fifty millimetres, in the brain sinuses seventy to eighty millimetres. The pressure in the veins of the neck is almost negative, hence the force tending to empty the cerebral veins is very great. The cerebro-spinal fluid fills up any intracranial space left by the brain and its vessels. When the brain shrinks, as in old age, this fluid amounts to half a pint, but ordinarily there are not more than two ounces.

The blood-vessels are subject to four principal forms of disease—aneurism, rupture, embolism, and thrombosis. But as ruptures and thrombosis are often due to aneurisms, and as emboli sometimes cause aneurisms, these four pathological changes are not in reality so very distinct.

With reference to the etiology and diagnosis of their conditions, modern research has brought out some interesting facts. Professor Gerhardt believes that not only aneurisms, but other forms of arterial and brain disease, are much more often caused by traumatisms than is generally believed. Among 131 cases collected by Killian only 8 were put down as due to traumatism, a proportion which Gerhardt thinks too low.

The great majority of aneurisms are due to endarteritis. This endarteritis is itself due to excessive mental and emotional strain, and the use of alcohol, combined with the degenerative changes of old age. Among 136 cases of cerebral aneurisms in Gerhardt's clinic (*Berlin. Klin. Wochensch.*, May 2, 1887), 42 occurred between the ages of fifty and sixty ; 94 between forty and eighty.

Cerebral aneurisms may occur, however, in children, and then without a preceding endarteritis. In these cases Ogle and Ponfick have shown that the aneurisms are due to embolism—an important pathological fact. Syphilitic disease of the arteries may cause aneurism also. In twelve per cent. of Heubner's cases of syphilis of the cerebral vessels aneurisms were found. These aneurisms are usually on the basilar or vertebral arteries, and account for some of the peculiar bulbar symptoms in brain syphilis. Brain aneurisms most frequently affect the basilar artery, next the artery of the Sylvian fissure, and then the internal carotid. Aneurism of the vertebrals is not excessively rare, and causes symptoms somewhat resembling bulbar paralysis.

Emboli lodge on the left side oftener than the right, in the proportion of two to six. The preference of the left side exists not only for the carotid and middle cerebral, but also for the vertebral, arteries. Emboli lodge in the vertebral because at its entrance to the basilar there is a slight constriction, so that the calibre is diminished one-fifth. Hence we have emboli in the vertebrals, but only thrombi in the basilar. This narrowing is greater in the left than the right artery.

Among 300 sufferers from valvular heart disease Spuling found that embolism had occurred in 84, and cerebral embolism in 15 of them. It may be laid down as a rule, then, that five per cent. of persons with valvular lesion of the heart have brain embolism. The majority of these occur on the left side, and usually enter the artery of the Sylvian fissure. Two-thirds of the cases of embolism occur in women, while hemorrhage affects men to a greater extent. The preference of embolism for women is due to post-partum accidents, and, contrary to Gerhardt's statement, the fact cannot be used as a helpful one in diagnosis. Loss of consciousness is the rule in apoplexy, but is present in only one-third of the cases of embolism. In this latter condition the absence of premonitory symptoms, the presence of aphasia, and the milder type of paralysis point to embolism.

Cerebral hemorrhages can be produced by a very great variety of diseases, *e.g.*, scurvy, leukæmia, chlorosis, pernicious anæmia, morbus Brightii, and pertussis. Occurring in these diseases the vessel rupture is due to the combined influence of a diseased and weakened vessel-wall and increased blood pressure. In such conditions one does not expect to find miliary aneurisms, which are so common in cerebral hemorrhage occurring under other conditions.

That it is small aneurisms (0.2 to 1.0 millimetre in diameter) which, by rupturing, are the direct cause of cerebral hemorrhage in most cases, is generally admitted. These aneurisms are found with decreasing frequency in the thalamus, corpora striata, cerebellum, centrum ovale, cerebral peduncles, and medulla. They are produced by an endarteritis. Other diseases, however, may weaken the vessel-wall and lead to its rupture. Prominent among these is syphilis, which was a certain factor in twenty per cent. of sixty-three cases examined by Gerhardt.

Thrombosis comes from exhausting or septic diseases,

and from thickening and stenosis of the arterial walls, such as occurs in syphilis and tubercular disease. Thrombosis plays an especially important rôle in brain syphilis and in senile alcoholic cases in which the arteries are thickened and atheromatous and the heart feeble.

THE SYMPATHETIC NERVOUS SYSTEM.

Not many years ago it was orthodox teaching to describe the nervous apparatus of the body as consisting of two great systems, the cerebro-spinal and the sympathetic. The former was said, in general terms, to preside over the functions of *animal* life; while the latter concerned more definitely the vegetative functions—that is, nutrition in its broadest sense. It was, of course, taught that these two systems acted harmoniously, one being voluntary, and the other involuntary.

More careful anatomical and physiological investigations have given us a somewhat different view. We now regard the sympathetic system, so called, as but a division of the cerebro-spinal, and not entitled to the position of a separate standing. This aspect of the case has been elaborated by Dr. Gaskell, in a recent course of lectures before the Royal Institution in London. He claims that no new nerve-fibres arise in the so-called sympathetic ganglia. The fibres destined to them from the cord come from the inner portion of the posterior horns, and inner portion of the gray matter. They are, of course, medullated; but in passing through the ganglia they lose their medullary sheaths and divide into smaller strands. The outer portion of the posterior horns and the outer portion of gray matter in the cord are more intimately concerned with the voluntary muscles. The intimate relations of these two central areas, which are really but divisions of one, give a corresponding association of symptoms in both voluntary and involuntary muscles. Hence the association of visceral pains in connection with spinal lesions.

The more physiological research is carried on, the more intimately is the nervous system seen to be connected with many vital processes, which have hitherto seemed to localize themselves in single organs or groups of organs. A great field may lie open for internal localization, corresponding or analogous to the cerebral surface areas.

VACCINATION AGAINST TYPHOID FEVER.

It is not at all beyond the bounds of probability that medical science will yet discover a safe "vaccine" against typhoid fever. Already some progress has been made in this direction. Recent researches by Brieger, Sirotinin, and by Beumer and Peiper, have shown that typhoid bacilli secrete a peculiar poison or ptomaine which Brieger, its discoverer, calls "typhotoxine." This substance injected into animals seems, in some cases, to have produced lesions similar to those of typhoid fever in man. Furthermore, it is apparently shown that the bacilli themselves are not the direct harmful agents in typhoid, for sterilized cultures are found to be as injurious as non-sterilized. Hence it is believed that the symptoms of artificial (as well as of true) typhoid are those of intoxication rather than infection, if such a distinction can be drawn. The *London Medical Record*, in summarizing the recent work in this direction, says that "Beumer and Peiper, in their last experiments, had been obliged to use repeatedly the same animals. They, therefore, were enabled to make typhoid revaccinations, and obtained the curious fact that the results of these were either negative or very doubtful. E. Fraenkel and Simmonds, as well as Sirotinin, in their experiments, have likewise observed that the first infection insured to these animals a certain immunity, owing to which the subsequent reinfection either produced but few or no morbid symptoms at all.

"Reviewing these interesting experiments, the results and conclusions arrived at by their authors are the following:

"1. The symptoms and alterations observed in animals in which cultures of typhoid-bacilli had been injected are due to the toxic substances secreted by these bacilli.

"2. The noxious germs, which secrete the typhotoxine, are reproduced in the intestinal canal. From these the ptomaine is taken up by the circulation and carried to all the organs liable to be affected by this poison.

"3. It is most probable that the same takes place in abdominal typhoid fever of man.

"4. A first infection insures immunity against the injurious effect of a later infection, even of large quantities of the toxic substance.

"5. Further experiments and careful clinical investigations are necessary in order to establish a scientific support of the theory of immunity from injections of sterilized cultures containing not more than a determined quantity of typhotoxine.

"6. In case this theory be an ascertained fact, the reproduction of the same immunity in man would be justified by commencing with very minute doses of typhotoxine, which would be gradually increased according to the results obtained."

WHY THE TEETH ARE DETERIORATING.

Dr. Julius Pohlman, in an interesting article on "The Human Teeth Viewed in the Light of Evolution" (*The Medical Press of Western New York*), shows the inadequacy of many of the explanations of the poor teeth of modern times. He believes that people have poor teeth as they have poor muscles, because they are not used enough. The food of the present day is cooked, softened, and hard particles removed, children are brought up on soft foods, and in general there is a tendency to allow the teeth to lapse into a harmful desuetude.

The cure would be therefore to make children and adults eat crusts and hard bread, to chew their food into fine particles without having it previously minced—in fine, perhaps, to spend a few years in a third-class boarding-house or an Adirondack hotel.

A LITERARY WANT.

Hardly a year passes that we are not favored with some new work treating of the history of medicine. A glance at these books shows that they are mainly compilations, and all from the same sources, viz., Sprengel, Littré, Pettigrew, Moir, and Friend. The historical orations which so often adorn our annual society or

college celebrations betray always a perusal of the same useful works, supplemented, perhaps, by Watson or Dunglison. In Germany there is being published a biographical dictionary of medical men, but it covers only a narrow field. Mr. Fort, of London, and M. Thomas, of Paris, have lately published some original contributions to the subject of medical history. But there is still lacking a complete and philosophical work on the history of medicine—a book which will show original study, a knowledge of modern historical methods, and an acquaintance with the numerous additions to historical and sociological knowledge which have been made in the past fifty years. The history of medicine is the history of civilization, and it furnishes a worthy subject for the labors of the scholar and the interest of the student.

News of the Week.

Our Report of the International Medical Congress is completed in this issue. We have spared no pains nor space in presenting an exhaustive *résumé* of all that was done at the meeting in Washington, and trust that it has been satisfactory to our readers. Much that appears is not specially new to most of our patrons, but it is part of the official work of the Congress, and as such must find its proper place.

Natural and Artificial Infants' Food.—Professor Albert R. Leeds states that out of every one hundred infants fed on mothers' milk, statistics showed that about eight die at the end of the first year; out of one hundred wet-nursed, eighteen died; and of one hundred fed on "infant-foods," fifty-one died by the end of the first year. He advocated the use of cow's milk diluted to the standard of human milk. Professor Leeds' statements are, we believe, somewhat misleading. Infants intelligently fed have nearly as good a chance of life with artificial as with natural food.

The College of Physicians and Surgeons.—Inaugural Exercises of the new building of the College of Physicians and Surgeons, 437 West Fifty-ninth Street, will be held on Thursday, September 29th, at 3 P.M. There will be an Historical Sketch of the College, by J. C. Dalton, M.D., President; an Inaugural Address, by Joseph H. Choate, Esq., Trustee; and the Presentation of Portrait Busts, by William H. Draper, M.D., Trustee. The profession is invited to attend.

Hospital for Incurables.—The corner-stone for a new hospital, the St. Joseph's Hospital for Incurables, was laid on September 14th. The new structure is located at 143d Street. It will contain two hundred and fifty beds.

Bequests to Hospitals.—The late George E. Downs, of Canton, Mass., has bequeathed to the New England Hospital for Women and Children $10,000; to the Children's Hospital, $2,000; to the Massachusetts Homœopathic Hospital, $5,000.

A Kind of Laparotomic Quincentennial was celebrated by Professor Nussbaum recently on the occasion of his performing his five-hundredth laparotomy. His pupils prepared a floral arch containing the figures "500," and placed it over the entrance to his clinic.

Dr. Fordyce Barker tendered a reception to the Fellows of the American Gynecological Society and foreign delegates to the Congress, on Tuesday evening. A large number of New York physicians was present.

Fluid Extract of Pichi in twenty-drop doses is a valuable addition to our remedies for the treatment of vesical catarrh, according to Dr. T. G. Comstock, in the New York *Medical Times*.

Counter-prescribing in Illinois.—Illinois druggists are very indignant, says the *Sanitary News*, because Section 10 of the new Medical Practice Act prohibits "counter-prescribing." At a recent meeting the State Pharmaceutical Association denounced the act in unmeasured terms, and appointed a committee to prepare an amendment to the act which should wipe out the section, and instructed the committee to use its best efforts to have the amendment passed by the legislature.

The Contagium of Scarlet Fever.—In a careful critical review of the researches and claims of Dr. Klein and Dr. Edington regarding the contagion of scarlet fever, Dr. Thin has shown that the identity of this contagium with that found in a certain disease of the cow's udder is not established. The view that scarlet fever may be derived from the cow is therefore still lacking demonstration. The claim of Dr. Edington to have discovered the specific virus is also shown to be wanting in positive proof.

Doctor Pedlers.—Doctors are so scarce in Russia that the *Nijegorodsky Listok*, of May 21, 1887, recommends young medical men to provide themselves with a box of drugs and chemist's utensils, and to walk from one Russian village to another, as do ordinary pedlers, in order to prepare pills, mixtures, etc., at every village.

New Regulations by the Health Board.—During the past week the following resolutions have been adopted by the Health Department:

Resolved, That Dr. W. DeF. Day be and is hereby relieved of the duties of Register of Records of this Department.

Resolved, That Dr. R. S. Tracy be and is hereby transferred from the position of Chief Sanitary Inspector to that of Register of Records, and that his salary be fixed at $3,000 per annum.

Resolved, That the position of Chief Inspector in charge of the Sanitary Police be and is hereby abolished, and that Willard Bullard be transferred to the position of Chief Sanitary Inspector, *vice* Dr. Tracy transferred to Division of Vital Statistics, and that the Sanitary Police report to Chief Sanitary Inspector Bullard.

Resolved, That on September 19, 1887, the Medical Sanitary Inspectors of this Department be transferred to the Division of Contagious Diseases, and that on that date they do report to Dr. J. B. Taylor, Chief Inspector of that Division, for instructions.

Resolved, That the Chief Inspector of the Division of Contagious Diseases be and is hereby directed to report to this Board at once, a comprehensive and concise plan for the instruction of the Medical Sanitary Inspectors in the performance of their duties, whereby a systematic and persistent war can be waged on all forms of preventable and contagious diseases in this city.

Resolved, That from and after January 1, 1888, the Medical Sanitary Inspectors be graded as follows:

First Grade.—This grade shall consist of all such Medical Sanitary Inspectors as may thereafter become connected with this branch of the Department, together with all such Medical Sanitary Inspectors as are then connected with this branch of the service who have served the Department satisfactorily in the capacity of Medical Sanitary Inspectors for three years or less. The salary of this grade shall be $1,200 per annum.

Second Grade.—This grade shall consist only of such members of the first grade as shall have served satisfactorily in that grade for the term of three years, together with all other Medical Sanitary Inspectors of this branch of the service as at present constituted. The term of service of each member of this grade shall be two years, and the salary shall be $1,500 per annum.

Third Grade.—This grade shall consist of only such Medical Sanitary Inspectors as shall have served satisfactorily in the second grade for the full term of the same. The term of service of each inspector of this grade shall be three years, at a salary of $1,800 per annum.

Fourth Grade.—This grades hall consist only of such of the members of the corps as shall have served satisfactorily in the third grade for the full term of its service. The salary of this grade shall be $2,000 per annum.

Obituary.

ALONZO CLARK, A.M., M.D., LL.D.,

NEW YORK.

On September 14th Dr. Alonzo Clark died at his home in this city. He was in his eighty-first year, and had practised his profession for over fifty years. For nearly the same period of time he had been a professor and teacher in our medical colleges, and at the time of his death there were few physicians who had helped to equip so many students for their professional career. Dr. Clark was born in Chester, Hampshire County, Mass. It is stated that he never knew the exact date of his birth. He believed it to be 1807, but others had told him that it was 1808. During his earlier years Dr. Clark attended the public schools of his native town. In 1824 he entered Williams College, being graduated in 1828. He at once began his medical studies, and in 1835 was graduated from the College of Physicians and Surgeons of this city. Soon after graduation he was appointed Professor of Pathology and Materia Medica in the Vermont Medical College at Woodstock. After a few years spent in lecturing there, he removed to this city and entered upon active professional duties. His success as an instructor had become so marked that he was soon made Professor of Physiology and Pathology in the College of Physicians and Surgeons. This position he held from 1848 until 1855. Meantime he was gaining a high position as a practitioner of special ability in the diagnosis and treatment of disease.

In 1855 Dr. Clark was appointed Professor of Pathology and Practical Medicine in the College of Physicians and Surgeons, and in the same year he became Visiting Physician to Bellevue Hospital. In 1853 he was elected President of the New York State Medical Society. In 1861 he was made President of the Medical Board and Consulting Physician to St. Luke's Hospital. He was Consulting Physician to the Northeastern and also to the Northern Dispensary. In addition to the State Medical Society he was a member of the American Medical Association, of the New York Medical and Surgical Society, of the New York Society for the Relief of the Widows and Orphans of Medical Men, of the New York Pathological Society, and of the New York Academy of Medicine.

Dr. Clark never attempted surgical work. He took a peculiar interest in pathology, and was one of the pioneers in that branch of medical science in this country. His contributions to the pathology of yellow fever, cholera, and of pulmonary and cardiac disorders made him at one time the foremost pathologist of the country. By his work and enthusiasm he gave impetus to the study of a branch previously not carefully cultivated here. Dr. Clark was early an adept in the use of the microscope and in its application to the study of disease.

It has been customary to give to him the credit of devising the opium-treatment of peritonitis, a method now universally adopted, and one that has been of infinite service. It is certain that Dr. Clark first systematically used and taught this method. If he had done nothing else, he would have been entitled to the lasting gratitude of mankind.

Dr. Clark made numerous contributions to medical literature, many of the most important being published in THE MEDICAL RECORD. He never wrote a systematic treatise, though three years ago a small work on Diseases of the Heart, composed of a series of didactic lectures, was published.

Dr. Clark was a successful and popular lecturer and teacher. He was not eloquent or rhetorical, but told the story of disease in a simple and clear manner, enlivened with touches of dry humor. He was decidedly conservative as to the physician's powers both in diagnosticating and curing disease.

Personally, Dr. Clark was tall, of fine presence, and courtly manners. His was the temperament that scorned the petty quarrels and jealousies that attach themselves to the careers of so many prominent and more aggressive men. He made few enemies, but many friends.

A NEW THEORY OF RESPIRATION.—Herr von Fleischl has recently brought forward the following new theory of respiration at the K.K. Gesellschaft der Aerzte in Vienna. It rests upon the fact that when liquids holding gases in combination are subjected to mechanical agitation a certain proportion of the gaseous molecules are set free, or else form a much looser combination with the constituents of the liquid than before; in other words, chemical combination is changed to a mere solution. This fact is perfectly consistent with the fundamental principle which underlies the existing theories of respiration, that hæmoglobin forms with the oxygen of the air a compound called oxyhæmoglobin. But Von Fleischl asserts that this combination, as first formed, is too stable for the tissues to overcome, even for the tissues which have a special affinity for oxygen, *i.e.*, are oxidizable; but that when the blood, after passing through the lungs, arrives in the left ventricle laden with oxyhæmoglobin, it is there subjected, by the contraction of this ventricle, to a shock or agitation which sets free a certain portion of oxygen, and thus renders it serviceable for the tissues. Blood which has assumed the venous character only holds about two-thirds the amount of oxygen which arterial blood contains, and blood having only this proportion of oxygen is as useless for oxidizing purposes as blood during asphyxia, or as quicksilver.—London *Medical Record.*

THE OPIUM HABIT.—According to a paragraph which is going the rounds of the daily press, there are ten thousand opium eaters in Iowa, a large majority of them being women. This estimate is as likely to be below as above the actual figures.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 4 to September 10, 1887.

BYRNE, MAJOR C. C., Surgeon. Detailed as a member of the Army Retiring Board in Washington City, *vice* Captain Washington Matthews, Assistant-Surgeon, relieved. Par. 2, S. O. 208, A. G. O., September 7, 1887.

O'REILLY, MAJOR R. M., Surgeon. Ordered to proceed to Fort Niagara, N. Y., on public business, and upon completion thereof to return to his proper station, Washington, D. C. Par. 10, S. O. 205, A. G. O., September 3, 1887.

PERLEY, CAPTAIN H. O., Assistant-Surgeon. Ordered to accompany battalion of the Twenty-third Infantry from Fort Wayne, Mich., to Chicago, to participate in the International Military Encampment to be held in that city in October next. Par. 1, S. O. 191, Headquarters Division of the Atlantic, September 8, 1887.

BANISTER, W. B., First Lieutenant and Assistant-Surgeon. Granted leave of absence for one month, with permission to apply for extension of one month, to take effect upon arrival at Fort Lowell, of Assistant-Surgeon J. B. Girard. Par. 4, S. O. 91, Headquarters Department of Arizona, August 29, 1887.

SUTER, WILLIAM N., First Lieutenant and Assistant-Surgeon. Ordered to accompany Battery E, Third Artillery, from Washington Barracks, D. C., to Philadelphia, on the 14th inst., to participate in the military parade, during the celebration of the centennial of the adoption of the Constitution, September 15, 16, and 17, 1887. Par. 3, S. O. 191, Headquarters Division of the Atlantic, September 8, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and death from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 10, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	47	13
Scarlet fever	47	9
Cerebro-spinal meningitis	3	3
Measles	6	0
Diphtheria	81	36
Small-pox	6	1
Yellow fever	0	0
Cholera	0	0

TREATMENT OF INFANTILE DYSPEPSIA BY LACTIC ACID—THE CAUSATION OF THE GREENISH DISCHARGES WHICH CHARACTERIZE THIS AFFECTION.—Hayem, in a communication recently made to the Paris Academy of Medicine, claims signal success in the treatment of gastro-intestinal irritations of infants, especially such as are attended with green discharges, by lactic acid (*The Boston Medical and Surgical Journal*). He employs a two per cent. solution, of which a teaspoonful is given to the infant a quarter of an hour after nursing. From five to eight such doses, representing about half a gramme (or seven and a half grains) of pure lactic acid, are administered during the twenty-four hours. The effects of this treatment, it is said, rapidly show themselves. The vomiting (where vomiting exists) ceases almost immediately, the diarrhœa lessens in frequency and amount, and the discharges soon take on their natural yellowish hue. Hayem was led to adopt an acid treatment in these cases from having frequently tested the vomited and fecal matters, and found them neutral or alkaline. In these discharges, moreover, he detected the constant presence of a strange microbe, clustering in masses. This microbe he has been able to isolate and cultivate in gelatine-peptone, and, by experimental researches undertaken with his interne, Lesage, he thinks that he has conclusively shown that these masses of bacteria produce the greenish matter by a sort of excretion. This microbe, moreover, can only live and multiply in an alkaline medium, and the etiological conditions which bring about the gastro-intestinal dyspepsia of infants, by modifying the secretions of the alimentary canal, make it a fit habitat for the microbe, which now becomes the principal factor in the graver accidents which characterize the disease. These micro-organisms, it has been found, soon perish in an acid medium. Hayem first tried dilute hydrochloric acid with some success, but soon found that lactic gives the best results. This acid, he says, acts in two ways: it combats the dyspeptic condition by giving the stomach the degree of acidity required for healthy digestion, and it sterilizes the germs of the bacillus, thus effectually antidoting the pernicious effects of the latter on the digestive tube. Lactic acid is, moreover, pleasant and easy of administration. The contagiousness of this gastro intestinal affection with green discharges is a natural corollary from the fact, real or assumed, of its bacillary origin. This contagiousness, Hayem affirms, is proved beyond the possibility of a doubt by clinical experience, and when once a case of the kind enters the wards of the children's hospitals, an epidemic of the disease is sure to follow. Recently, Damaschino claimed priority over Hayem in the discovery of the microbe supposed to be the causal agent in the diarrhœa with green discharges in young children, and produced microphotographs which he presented three years ago to the Society of Biology, and which he affirmed to be representations of the same microbe described by Hayem as causative of the disease in question. These bacilli are of characteristic forms and dimensions, and constitute an important morphological element of the stools of young diarrhœic patients. They are the more numerous, the more severe the affection, and in three grave cases of green diarrhœa they presented the appearance of pure cultures in the microscopic preparations. In the fresh state they are animated by rapid movements. These bacilli disappear as the disease diminishes in intensity, and the discharges take on their natural yellowish hue. Hayem, in replying to the communication of Damaschino, did not deny the value of the discovery of the latter investigator, of which he (Hayem) was ignorant at the time of the presentation of his paper, only Damaschino had not proved any causal relations between the masses of rod-like forms which he had found in the green discharges of infantile diarrhœa and the disease. This proof, Hayem claimed, had been furnished by his interne, Lesage, who had isolated and cultivated the specific microbe, and, by introducing the pure products of his cultures into the digestive canal of animals, had reproduced the disease, with the identical green discharges. The report of these interesting experiments Hayem has promised to give at an early day.

THE PROPHYLAXIS OF SYPHILIS IN FRANCE.—The Paris correspondent of the *Lancet* writes as follows on this topic, which has recently engrossed the attention of the Académie de Médecine. The disease is, indeed, disastrous and dangerous through its multiple consequences, individual, social, and hereditary. It is, with alcoholism, one of the gravest social evils of the present time. It is looked upon in society as the result of a series of successive contaminations rather than the consequence of a single contagion, and it is therefore supposed to be evidence of an ill-spent life of debauch. This view is erroneous. Syphilis is contagious like all other contagious diseases, *i.e.*, it results not from repeated infec-

tions, but from one alone. There are numbers of people who acquire the disease from what Professor Fournier terms "moral virtuous," or purely accidental, contagions, but syphilis, both deserved and undeserved, has a common origin. The infection of a virtuous wife and the contamination of a child may most often be traced back to disease of a prostitute; hence the consequence that to combat syphilis in the latter is to protect both the virtuous wife and child. Public interest requires that such an evil should be repressed by general measures capable of reaching it at its source. These measures are of three kinds: 1. The extension of the disease may be restrained by administrative or police regulations to prevent provocations in the public thoroughfares, by what is called the inscription or registration of prostitutes, which brings them under police and sanitary supervision; by the inspection of those establishments which, under the names of taverns and drinking-bars, are in reality nothing else than houses of assignation. 2. Syphilis may be checked, in the second place, by treatment by hospitalization, *i.e.*, by extinguishing its germs of contagion. 3. It may be combated not less efficiently by teaching the rising medical generation, more thoroughly than has hitherto been done, all that concerns the symptoms of this disease in its different forms, its social dangers, and its treatment. As regards measures of administrative prophylaxis, the Commission was unanimous in declaring that prostitution constitutes a public danger by the contagion which it disseminates in the population. It is therefore indispensable, both on hygienic and moral grounds, that it should be supervised, and, if necessary, repressed, by the public authorities. The measures proposed for this purpose by M. Fournier are briefly as follows: In the first place, public provocation should be considered as a misdemeanor. This measure, entirely in accordance with public opinion, would have the effect of removing habitual prostitutes from the arbitrary jurisdiction of the police. Those convicted of the offence should be *inscrites*, and subjected afterward to periodical examination. Special hospitals for the treatment of venereal diseases should be created for the large centres of population, and the medical direction given to specialists, who should engage to remain in charge for at least five years; but in respect to the army, the Commission proposes that lectures on syphilis should be delivered to the soldiers to make them understand the dangers of contagion; that the men should never be punished for having contracted venereal disease; and that treatment should be continued after the soldier has returned to duty. Professor Fournier's final recommendation is for the benefit of society at large. Henceforth no wet nurse should be allowed to receive an infant without a medical certificate that the parents are free from syphilis.

Infanticide or Homicide?—The following case is reported in the *Münchener Medizinische Wochenschrift:* A physician was called to attend a tradesman's wife in her confinement. The presentation was a shoulder one with prolapse of an arm. After an ineffectual attempt to turn, the arm was cut off; then followed another ineffectual attempt to turn, after which the other arm was amputated and the lower jaw torn out. Even after this he did not succeed in extracting the child, and another practitioner was called in, who succeeded in delivering the woman. The first practitioner was cited before the Court, where the experts, professors, and practitioners expressed the unanimous opinion that the child had been killed by the injuries inflicted upon it, and that the contention of the physician, that the child was already dead before dismemberment, rested upon indications that were not scientifically justifiable. There were no just reasons for killing the child, and the practitioner had improperly failed to persist in his efforts to turn. After negligence had been incontestibly proved by the opinion given, the defendant claimed that the case did not come under paragraph 222 of the German Strafgesetzbuch (negligent killing), but under paragraph 230 (negligent bodily wounding). The former referred to negligent homicide; the fœtus, however, up to the time of dividing the cord, was a part of the mother's body, so that the case was only one of wounding. In opposition to this, the Court ruled that the law recognized the vital existence of the fœtus, and protected it as a human being, at an earlier period, viz., as soon as a part of the child became *visible* outside the vagina; paragraph 218 defined killing of the fœtus *in utero* as fruit-killing (*Fruchttötung*), while paragraph 217 recognized the killing of a child *in* or immediately after birth as the killing of a human being (homicide). The Court, therefore, held the accused guilty of homicide by negligence, and condemned him to several years' imprisonment. An appeal was not allowed.

Not a Well-built Word.—Among the frantic attempts to muddle medicine with jaw-breaking technicalities, we find one which resulted in the word "syggignoscism." If we had found it as coming from Sweden or the Sandwich Islands, our astonishment would have been less.—*Medical Review.*

Hydrogen Dioxide.—Referring to a paper on this subject by Dr. Blyer, in The Medical Record, Mr. Thomas Latham calls attention to the difficulty of obtaining a solution of constant strength. The solution is usually put up in five-pound bottles, and each time that the bottle is opened an escape of gas takes place. He suggests that the manufacturers put it up in two-ounce bottles securely corked, and this could then be used to prepare a diluted solution for use in which the H_2O_2 would remain permanently dissolved. The writer further states that it is incorrect to use the term "ozonized" in connection with this solution. The oxygen evolved by its splitting up is not in the form of ozone. Schonbein even proposed for it the name, antozone.

Contracted Kidney in Childhood.—Förster has published two cases which he considers as examples of contracted kidney, although they presented during life symptoms closely similar to those of diabetes insipidus. The patients, brother and sister, belonged to a family with a markedly neurotic history. The father was syphilitic and suffered from locomotor ataxia, while both parents of the mother suffered from diabetes mellitus. The first symptom noticed in the boy was the onset of great thirst and diuresis at the age of four and a half years. The urine became as much as seven pints in the day. The specific gravity of the urine varied from 1.004 to 1.010. There was no sugar, and, at first, no albumen, though this was found a short time before death. The diuresis continued, while the patient lost weight and developed a pale and sickly complexion with a dry skin. The mental qualities were unaffected. The child died when nine and a half years old, five years after the commencement of the illness. Death was preceded some weeks by increasing somnolence, twitchings of the legs, incoördinate gait, and increase of the tendon-reflexes. The post-mortem, which was performed by Birch-Hirschfeld, showed a thickening of the ependyma of the fourth ventricle, flattening of the pons, which was sclerosed at its junction with the medulla. There were sclerotic patches in the posterior cornua of the spinal cord. The left ventricle was hypertrophied, and the kidneys were contracted, especially in the cortex, the capsule being adherent. The other patient, in whom a post-mortem was not performed, was taken ill at the age of four and three-quarter years, with symptoms similar to those presented by her brother. The cause of the malady was practically the same, except that albumen was found in the urine at an early stage, and that it increased in quantity. Förster mentions the close analogy of the cases with the symptoms presented by diabetes insipidus, but draws attention to the differences, viz., that the quantity of daily urine was not as great as that of diabetes insipidus, and that the specific gravity was also higher than occurs in that disease.

CEREBRAL CONGESTION FOLLOWING REMOVAL OF THE UTERINE APPENDAGES.

BY H. C. COE, M.D.,

NEW YORK.

SIR SPENCER WELLS said, fifteen years ago, in writing of the after-history of the patients upon whom he had performed laparotomy: "As a rule, in all statistical returns from hospitals, the bare fact of death or recovery is all the information that is given, and any attempt to follow up the successful cases afterward is found to be excessively difficult." In spite of the vast number of statistics that have been published since this was written, it applies equally well to the present stage of abdominal surgery. It cannot be denied that laparotomists can give us only meagre information concerning the condition of patients one or more years after recovery from the operation. It is unfortunate that our knowledge regarding the general, as well as local, phenomena which appear in women after removal of both tubes and ovaries is derived rather from isolated cases than from carefully collected groups. While the phenomena attending the natural menopause have been thoughtfully studied, and have formed the subject of elaborate monographs, those dependent upon the artificial climacteric, if noted at all in special treatises, are dismissed in a few words as insignificant. The general impression given by laparotomists is that the removal of the uterine appendages is seldom followed by any general disturbances—in fact, that the system accommodates itself at once to the sudden and rude interruption of the menstrual function.

The reader who recalls the profound systemic disturbances that attend the gradual cessation of ovulation will be puzzled to account for this discrepancy. Theoretically, it would seem as if a young woman in the prime of her sexual activity ought to be more seriously affected by the artificial induction of the menopause than one in whom the gradual disappearance of the function keeps pace with the general senile atrophy. While it is a fact that the majority of patients recover without any serious complications, careful investigation will show that irregular or periodical metrostaxis, constant or recurring pelvic pain, "flushings," neuralgiæ, and various minor vaso-motor disturbances, such as are noted at the natural climacteric, appear for a shorter or longer period in not a few, and, moreover, that they are still present one or two years after recovery from the operation.

I was led to describe briefly a phenomenon occasionally observed in these cases by the remark of a young woman to whom laparotomy was proposed as a possible means of relief from intractable dysmenorrhœa. She did not dread the operation, she said, but a friend of hers had had her tubes and ovaries removed a few years before, and had suffered ever since from frightful attacks of congestive headache at the menstrual period; that she considered her present condition as far worse than the former one. Having had under constant observation during the past three years a patient with the same symptom, I was able to understand that the nature of the trouble had scarcely been exaggerated. It may be safely stated that cerebral congestion is a well-recognized sequela of the operation referred to, and that it would be found to be more frequent than is commonly supposed if we were able to follow up these cases and obtain accurate reports of their general, as well as local, condition at the end of a few years. We are justified in using the expression "cerebral congestion" in this connection, not only because all the symptoms point to an increased determination of blood to the cranium, but because the congestion seems to be a vicarious one. As Tilt (and more recently Börner) has shown, this cannot be affirmed of the normal menopause, where the headache, flushing of the face, and other cerebral troubles are to be ascribed rather to vaso-motor disturbances than to actual congestion.

Olshausen ("Krankheiten der Ovarien") regards the symptom referred to in this paper as purely vaso-motor, and calls attention to the fact that the phenomena observed after castration do not, as a rule, appear with the periodicity of menstrual disturbances, but are relatively more severe and persistent than those observed in connection with spontaneous cessation of the flow. This, he adds, is to be ascribed to the suddenness with which the function of the ovaries is interrupted, while in senile involution the process is gradual.

While it is true that the nervous phenomena in question are commonly atypical—that is, they are not confined to the periods when the menstrual flow usually appeared—they are in many instances clearly aggravated at those times when increased pelvic congestion is indicated by local pain and metrostaxis, or "weeping from the uterus," as it has been termed by English writers.

The condition which I regard as cerebral congestion is also most marked at these pseudo-periods, as evidenced by severe frontal and occipital headache, vertigo, pulsation of the carotids, flushing of the face and neck, suffusion of the conjunctivæ, etc., symptoms which can hardly be attributed to "nervousness" alone.

It is vain to theorize regarding the cause of phenomena which are so little understood, since our data are not yet sufficient to allow of any positive scientific deductions. The duration of this distressing condition after removal of the appendages is uncertain, and this uncertainty should lead the laparotomist to express a guarded opinion when asked by the patient to fix a certain limit to her after-symptoms. The young woman to whom reference was made, whose periodical attacks of pelvic and cerebral congestion (assuming that I am correct in inferring the presence of this condition) is rather worse than better, although nearly three years have elapsed since her ovaries and tubes were extirpated. The pelvic distress may be attributed to the presence of adhesions, resulting from an attack of localized peritonitis following the operation, but the head symptoms of which she complains would certainly be explained as due to an increased determination of blood to the brain, if they were observed by a general practitioner.

Hegar noted the presence of menstrual molimina five years after castration, and Olshausen observes that "they often persist for several years."

The therapeusis in these cases is highly unsatisfactory. These are the women who haunt one's office and clinic, exhausting at once the patience of the gynecologist and his ingenuity in combining drugs. An injection of morphine may relieve them temporarily, but it is a dangerous makeshift, and may lead to unfortunate results. The bromides, perhaps, afford relief for a time, but they soon appear to lose their power. Electricity is a useful agent, a mild continuous current sometimes having a happy ef-

fect. It certainly relieves the pelvic pain, although I have not satisfied myself regarding the permanent results of electrical treatment in these cases.

It hardly seems justifiable to deduce a lesson from such a brief and imperfect sketch, in which I merely wish to call the attention of the general reader to certain puzzling phenomena in patients who have recovered from an operation which is now so common. The subsequent condition of such patients may be disappointing, not only to themselves, but to their medical attendants, who expected a more perfect "cure." The practical point is this: Whatever promises may be made to a woman who is about to submit to laparotomy for the removal of the appendages, with regard to the relief of her local trouble, the prognosis concerning the persistence of such general symptoms as have been described should be a guarded one.

PERIODICALLY RECURRING OCULO-MOTOR PARALYSIS.[1]

By ALFRED HINDE, M.D.,

SURGEON TO THE EYE AND EAR CLINIC, CENTRAL DISPENSARY; INSTRUCTOR IN EYE AND EAR DISEASES, POST-GRADUATE MEDICAL SCHOOL, CHICAGO, ILL.;

AND

HAROLD N. MOYER, M.D.,

LECTURER ON PHYSIOLOGY, RUSH MEDICAL COLLEGE; INSTRUCTOR IN NERVOUS DISEASES, POST-GRADUATE MEDICAL SCHOOL, CHICAGO, ILL.

This disease is not referred to in any of our standard text-books on general medicine or nervous diseases. A line in Strümpel states that Möbius has reported a case. Bastian's late work on "Paralysis, Cerebral, Bulbar, and Spinal," does not mention the disease.

The following briefly described case came under our observation in May last: T. S——, born in Sweden, aged twenty years; family history good, and free from neurotic heredity. Both parents living, and well, as are also all of her brothers and sisters. She was perfectly healthy until her seventh year, when the first of the attacks to be described occurred. She awoke one morning to find that she could not open her left eye, and on raising the lid the eye was seen to be turned outward. The paralysis was not associated with pain or vomiting, and followed a good night's sleep. After three or four days the eye opened as perfectly as ever, and the direction and movements of the eyeball were normal, and vision was perfect. On the morning of the attack a physician was called who gave some medicine, but the patient does not remember that he expressed any opinion regarding her condition. After about two months, during which time the eye was free from any symptoms of paralysis, she experienced a severe pain in the side of the head, accompanied by vomiting and vertigo. For about two days she was confined to her bed, the stomach rejecting all food, and on the second day, about thirty-six hours after the commencement of these symptoms, she suddenly found that she could not open the left eye, there was a divergent squint, as in the first attack. As soon as the paralysis appeared the vomiting, vertigo, and headache ceased. The paralysis of the eye muscles in this second attack lasted about one week, and was accompanied by slight paresis of the left arm; patient says that it felt heavy and weak, also that articulation was impaired, though she could think as acutely as before. The recovery from this attack was perfect. After an interval of three months, during which time she was perfectly well, the third attack came on, and was similar in every respect to the preceding, except that the arm and muscles of articulation were slightly more involved, and recovery was a little longer delayed. Four months elapsed when the fourth attack came on, which was substantially a repetition of the foregoing, the pain in the head being a little worse, as well as the vomiting and vertigo. During this attack she had left tinnitus aurium with occasional deafness, coincident with the headache and vomiting. From this time on the intervals between the seizures grew longer, the attacks occurring, on the average, once or twice each year until she was eighteen, when for a year and a half she was free from them. This period just preceded her journey to this country (June, 1886), and includes a time when she was an out-patient in an eye and ear infirmary. Since the onset of menstruation the seizures have borne no relation to this function. The first week after her arrival here she had an attack more severe than any former one, the pain and vomiting lasting three days, and the subsequent paralysis over a month. During the past six months she has had four attacks, the third one being very severe—the headache lasting nearly a week. The last attack came on about one month ago, before the eye had recovered from the effects of the preceding one. Following this last attack the paralysis has remained complete. Since the beginning of the disease the symptoms of each seizure have increased in severity, have been more prolonged, and the recovery from the paralysis has been lengthened and less perfect. After the fifth attack an undetermined degree of divergent squint and ptosis persisted during the intervals between the seizures.

Present condition.—When the patient is requested to open the eye, she succeeds in raising the lid about one line, divergent squint is present, and the pupil is widely dilated and immobile, the ring of the iris being 1½ mm. in width. The external rectus is normal, but no movements can be detected in the direction of motion of the muscles supplied by the third nerve.

Acuity of vision: R. E., $V = \frac{20}{xx}$, and all lenses are rejected. With this eye she reads No. I. Snellen at three to twenty inches, showing normal accommodation. L. E., $V = \frac{20}{lx}$, and no glass improves distant vision. With this eye she reads only No. X. Snellen at twelve inches without glasses, and with + 5.50 D. She reads No. I. Snellen with some difficulty at six and a half inches, thus showing a paralysis of accommodation. The ophthalmoscope shows a similar and normal fundus in both eyes. The ocular diagnosis is, therefore, a paralysis of the left motor oculi in all its branches; together with an amblyopia of the left eye without evident intra-ocular disease. The patient is an emmetrope.

At the present time, and while the ocular paralysis is complete, there is no weakness of the left arm, at least not greater, as compared with the right, than is usually found with right-handed persons. The tongue is protruded in the median line, and the facial lines are symmetrical. All the other cranial nerves are intact, and co-ordination, the reflexes, and other nervous functions are perfect.

The first case of this kind, so far as we have looked up the literature, was described by Gubler[1] in 1860. The patient suffered, at intervals of several years, from three separate attacks of paralysis of the right motor-oculi. The fourth attack was attended with delirium, coma, and death. The post-mortem examination revealed a plastic exudate along the base of the brain, the result of a chronic progressive basilar meningitis. The motor-oculi was surrounded by exudate. A small blood-clot was found in the pons. The cause of the meningitis was referred by Gubler, to an injury of the head, sustained by the patient some years previously.

The next case was observed by Mauthner,[2] in the klinik of Professor v. Graefe, in 1864. This patient, a girl, aged twenty, received a blow on her forehead in her third year, the scar of which still remains. A few months subsequently paralysis of right oculo-motor occurred, and was accompanied by headache and vomiting. This condition lasted some six months and then disappeared. The complex of symptoms returned at varying intervals for many years.

In 1876, A. Jacobi,[3] in an article on "Masturbation and 'Hysteria' in Young Children," reports a singular

[1] Read before the Chicago Medical Society, June 20, 1887.

[2] Vorträge, Heft 13, p. 398.
[3] American Journal of Obstetrics, 1876, p. 223.

case of functional paralysis of the third nerve. So far as we are aware, this is the only case of the kind recorded. A girl, nine years of age, was attacked with clonic convulsions followed by paralysis of all the branches of the right motor-oculi, excepting its intra-ocular fibres, as shown by the history. Ptosis was complete, the eye deviated outward, the pupil was somewhat dilated but responded to the light slowly. The child remained in this condition for weeks, but finally recovered. A second attack of convulsions was again followed by paralysis of the right oculo-motor, which was relieved by firmly pressing on the supra-orbital nerve and urgently commanding her to open the eye. The ptosis was instantly removed by this procedure. She remained well for a time, when a recurrence of the attack was relieved by similar treatment.

A recent letter from Professor Jacobi in reference to this case states that his notes extend only over one year after the last attack reported. Within the first five months of this period she had two attacks, in which there was only ptosis; no other branch of the nerve being affected. For the seven months before she was last seen there were no morbid symptoms.

In 1882 Saundby[1] published "A Case of Megrim, with Paralysis of the Third Nerve." The attacks began at twelve years of age and occurred at intervals of from six to nine months, until the age of nineteen. The attacks began with pain in the left side of the head, malaise, and constipation. The paralysis was total, except the sphincter of the iris.

In 1883 v. Hasner[2] published the case of a girl, seventeen years of age, who each month for the past four years had suffered from complete paralysis of the left oculo-motor. The girl began menstruating at the age of fifteen, and since that time the paralysis had always appeared with menstruation.

Möbius,[3] in 1884, described the case of a girl, six years of age, in which the attacks came on at the age of eleven months. They were accompanied by vomiting, headache, and vertigo.

At the November, 1884, meeting of the Berlin Society of Neurologists, Thomsen[4] related a case of periodical paralysis of the oculo-motor, in an epileptic, thirty-four years of age. The paralysis was accompanied by headache and vomiting, and had occurred once or twice each year since the patient was five years of age. The attacks bore no relation to the epileptic seizures. In the discussion Remak described a similar case; a man, twenty-two years of age, had had the attacks twice yearly since his twelfth year.

In 1885 a considerable number of observations were reported. Saundby[5] described an additional case of migraine with oculo-motor paralysis.

Before the French Society of Ophthalmologists, January 29, 1885, Perinaud[6] related the case of a woman, twenty-six years of age, who had suffered from this form of paralysis each spring since her seventh year.

D. Weiss[7] described a case with an autopsy.

Snell[8] reported a case to the London Ophthalmological Society. In the discussion Clark, Ormerod, and Beevor said they had seen similar cases.

W. Manz[9] described a typical case in August, 1885.

If the case of Jacobi be excluded we find that up to the present, and including our own, sixteen cases have been reported in which the clinical features resemble each other sufficiently to be classed together, and which constitute, so far as we know, the entire literature of the subject.

Möbius[10] would confine the term periodically recurring oculo-motor paralysis to those cases in which the disease begins during infancy or childhood, in which the paralysis is confined strictly to the branches of the third nerve, and is accompanied by vomiting and headache. If we admit the definition of Möbius our case can hardly be included among the typical ones, but it is to be remembered that the paresis of the left arm and muscles of articulation were only slight and transitory. At the present time there is no evidence of any weakness of these muscles. All the other features of the case are typical.

Regarding the pathology of the disease, the different authors vary widely. Saundby, Remak, and Perinaud refer the condition to a functional disturbance; v. Graefe and Manz think that in most of these cases there is a basilar meningitis. V. Graefe says, in reporting his case, that the blow on the head probably caused a fracture of the base of the skull, which may have been followed by an ostitis or an exostosis, which by periodical inflammatory enlargement pressed upon the nerve. Manz speaks of congenital malformations or arterial anomalies as a possible cause. In every case he thinks there is a chronic progressive anatomical lesion, and that it is not in any sense a "functional" disease. Möbius and v. Hasner think that in most of these cases the nucleus of the nerve is affected. It must be admitted that the theory of Möbius is well supported by the clinical history of the affection, and agrees fully with the evident central origin of our own case. The pain, from its character, he refers to an involvement of the descending band of fibres, passing to the fifth nerve (*absteigende Quintuswurzel*), which lies above and a little to the outer side of the nucleus of the third.

The clinical features in the beginning point strongly to a congestion, with or without compression, of the nucleus of the nerve, with more or less involvement of the surrounding parts. The pathological process later results in permanent anatomical changes. Möbius, however, distinctly admits that a peripheral (basilar) lesion may cause this form of paralysis.

Up to the present time three post-mortem examinations have been made in these cases. The first, that of Gubler, was hardly a typical one. The lesions in this case, so far as they affected the third nerve, were meningeal. The exudate extended, however, as far forward as the optic chiasma, and was especially thick about the circle of Willis and along the borders of the medulla. In addition, a blood-clot was found in the pons. The patient of Weiss died of phthisis. The lesion in this case was found strictly circumscribed, and involved the nerve-trunk itself; the nucleus was found free from change. The left oculo-motor, as it left the peduncle, was found flattened, grayish, and covered with numerous granulations, which, on microscopical examination, were found to contain numerous tubercle bacilli. The right oculo-motor, as well as all the other cranial nerves, were intact. The case of Thomsen, above described, has since died in the insane asylum at Dalldorf. The post-mortem examination, reported by Richter,[1] showed the right oculo-motor, where it passed through the dura, grayish in color and club-shaped. The left nerve was one-half the thickness of the right and white. A fibro-chondroma had separated the fibres of the right oculo-motor, but had not destroyed them. The nucleus of the nerve and all other portions of the brain were normal.

This last is the only typical case of recurring oculo-motor paralysis in which the anatomical diagnosis has been made. In each one of the three cases the lesion was peripheral, the nucleus remaining intact.

As a matter of fact, a careful examination of the literature of this disease would indicate that it may be of central (nuclear), peripheral, or even "functional" origin.

The prognosis is unfavorable. In only one case is there a history of anything like improvement.

HYDRATE OF TERPINA IN THE TREATMENT OF CATARRHS AND BRONCHITIS—TEREBENE.

By HALSTED BOYLAND, A.M., M.D., Etc.,

LATE PROFESSOR OF SURGERY IN THE BALTIMORE MEDICAL COLLEGE; LATE SURGEON FRENCH ARMY (DECORATED), ETC.

To the *Pinus australis* Michaux, the most important of the coniferæ, science is indebted for a remedy, not only possessing decided antiseptic powers, but also one that neutralizes fermentation, arrests the putrefactive process, and, what is of still greater value, destroys the lower forms of organic life, as they are found manifested in leptothrix, infusoria, vibrios, and bacteria.

The uses of turpentine in therapeutics seem to have been relegated chiefly to its exhibition in the tympanites of typhoid fever, to turpentine stupes in ileo-colitis, and to the occasional inhalation of a few drops of the oil in some cases of asthmatic dyspnœa. It is not, however, my intention to champion a remedy, although confessedly a valuable one, that is gradually being discarded by the profession, and finding a grave in the country grocery-store; but to direct attention, in the present brief paper, to an alkaloid of turpentine, namely, the *hydrate of terpina*, which has recently been found to be of considerable efficacy in the treatment of colds, catarrhs, bronchitis, and kindred diseases.

While practising in Italy, last winter, a case of obstinate bronchitis came to me for treatment. This case was one of long standing. The patient, a lady, had contracted the disease in the North of Europe, and had been previously treated with remedies usually prescribed in these cases, such as muriate of ammonia, extract of eucalyptus, and so forth, without having derived permanent relief therefrom. She consulted me in Florence, in which city, and just at that time, my chemist happened to show me a new alkaloid of turpentine, but recently prepared. This preparation, contained in a four-ounce glass-stoppered bottle, consisted of round, rhomboidal, and polygonal crystals, about the size of, and presenting much the same appearance as, those of the hydrate of chloral. It was the hydrate of terpina. A few of the more eminent Italian physicians had begun to prescribe it; they had, however, had no experience with it beyond a few cases, and their method of prescribing it did not seem to me to be the best. They were using invariably the pill-form, in doses varying from two to ten grains, every two, three, or four hours, according to the symptoms. Their pills appeared large in proportion to the quantity of the drug ordered, heavy, and uninviting; and fearing that, administered in this form, hydrate of terpina might not agree with the already weakened stomach of my patient, I determined to have it put up, and for the first time, in a mixture. Having ascertained by experiment that it was readily soluble in glycerine, my prescription was:

℞. Hydrate of terpina..... grs. xxiv.
Glycerine, C. P., q. s. ut f. solutio.
Syrup of lactucarium.....ad ℥ j.
M. Sig.—One teaspoonful every three hours.

After two doses there was already an amelioration in my patient's condition; the cough began to loosen; expectoration became free and easy in consequence of elimination by the bronchial mucous membrane; the skin became soft, moist, and natural on palpation; and there was a marked diminution in the bronchial whistling and râles. This improvement continued steadily for one week, during which time my patient was kept continually under the influence of the hydrate of terpina treatment. At the end of that time all physical signs of the disease had disappeared; a steel tonic was ordered her, and she left Florence shortly after, entirely restored to health.

In another case—one of catarrhal congestion of the larger bronchi—the mixture was administered in the same manner. In this instance there was a notable decrease of the mucous râles *ab initio*, and normal vesicular murmur could be distinctly heard in a very few days after. This was a case of recurrent bronchial affection, complicated by laryngitis, which had been treated as one of incipient catarrhal phthisis. It yielded readily to the hydrate of terpina treatment, in about the same space of time as the first case; the laryngeal trouble disappearing together with the bronchial affection.

Other cases, such as nasal and pharyngo-laryngeal catarrh from cold, have been treated by me with equal success by hydrate of terpina, exhibited in accordance with the formula given above.

In a case of night-cough from habit, two grains of hydrate of terpina, exhibited in a similar mixture at bedtime, had the effect of quieting the distressing cough on the first night until an early hour in the morning, when another dose was taken, and the patient slept quietly until day. The second night a single teaspoonful on retiring was all-sufficient to procure for the patient a comfortable night's rest. And so on the third night. At the end of ten days the medicine was entirely withdrawn, and there was no return of the malady. Bromide of potassium, tinct. opii, etc., had failed to relieve this case. It is probable, therefore, that hydrate of terpina possesses anodyne and hypnotic properties somewhat allied to those of hydrate of chloral, although my experience with it in cases of this nature has not been extended enough to enable me to speak positively on this point.

There is not the slightest taste or odor of turpentine about this valuable alkaloid. Taken in doses of ten grains, it produces in some patients a sense of fulness in the epigastrium, slight cerebral hyperæmia, accompanied by a feeling of stimulation, but these symptoms disappear directly the drug is withdrawn, and are due to reflex irritation of the sympathetic. Fifteen grains is the maximum dose given thus far. We should be cautious in prescribing larger doses, having always in mind the toxic effects, which would probably first be observed in the lungs and kidneys.

Terebene.—There is still another preparation bearing some chemical relation to the hydrate of terpina, viz., *terebene*. Terebene has been recently obtained in London from turpentine by distillation; it is a colorless liquid, volatile, and without the taste or odor of turpentine. This agent has been introduced into British practice during the last few months, and since the discovery and introduction of terpina by the Italians. Terebene is exhibited in doses of from two to ten minims on lump sugar or in a solution, and, like hydrate of terpina, has thus far been only prescribed in diseases of the respiratory organs. Owing to its form and volatility it cannot, of course, be administered in pills, an advantage possessed by the hydrate of terpina in suitable cases.

As late as the 12th of May last, terebene was unknown in most of the English pharmacies, and the specimen then shown me in London was vastly inferior as a preparation to the clear white crystals of the hydrate of terpina, likewise unknown in England. Up to that time, there had been no report of cases treated by terebene, nor has any, so far as the writer is aware of, appeared since.

One great advantage of the hydrate of terpina is its extreme cheapness. It has proved eminently satisfactory in my hands in every case in which I have used it, and I now prescribe it freely in all coughs, colds, and catarrhal affections, as well as in bronchial troubles generally, whenever elimination is indicated, and should advise its administration in asthmatic dyspnœa, in doses of two grains every fifteen minutes until ten grains had been given, or relief had been obtained. If these maladies depend upon a morbific germ or a bacillus, it is in the germicide properties of hydrate of terpina that we must seek for an explanation of its prompt and vigorous therapeutical action. From the foregoing, it is highly probable that we possess in the hydrate of terpina a rem-

edy that is destined to replace all preparations of the crude drug for internal exhibition, possibly hydrate of chloral as well, at least in some cases. It has none of the revolting attributes of turpentine, has already proved itself of great utility in the treatment of diseases of the respiratory tract, and must be conceded to be a valuable addition to the Pharmacopœia.

MANIA AND INEBRIETY.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

The following cases bring out the facts I wish to present:

A—— had two attacks of acute mania in five years and recovered. He was able to go on with his business (that of a builder), with no apparent evidence of incapacity. He was a temperate, hard-working man, but had a neurotic heredity. Premonitions of another attack of mania appeared, and arrangements were made for his removal to an asylum, when he suddenly disappeared.

Two weeks later he was found in a hotel, where he had been intoxicated every day, but attracted no attention in act or thought. His removal home was followed by a rapid recovery, and soon he went about his business as usual. Ten months later, after a period of excitement, he rushed to a saloon and drank to stupor. He was taken home, was delirious for a week, and then recovered. Two months after, he secreted himself in a saloon and drank for a week to stupor, then went home fully conscious and recovered. Since that time he has had three attacks in which the impulse to procure spirits was uncontrollable. On two of these occasions he was restrained, developing a confused mania of two weeks' duration and a long period of convalescence. On the third attack he ran away, and after four or five days' drinking to stupor returned, and recovered rapidly.

This question came up: Should he be allowed to go away and drink to great excess when the drink impulse came on? or, should he be restrained at home or in some asylum, where he would probably have mania?

The increasing frequency of these paroxysms, and the large business interests under his control, started inquiry as to his mental responsibility. Two medical experts found no indications of insanity or mental incapacity, based on an examination in the free intervals of his paroxysms. The drink-impulse was regarded as a moral lapse, and the mania appearing when he could not procure spirits as simulation.

In my opinion this man was insane, and the paroxysmal inebriety was only a symptom. His real mental condition was concealed, because he lived along accustomed lines of thought and act, and hence acted automatically, and could keep up a semblance of sanity without effort.

B—— came under my care, a neurotic by inheritance and a periodic inebriate. Nothing unusual was noted until the return of the paroxysm, when he ran away, and was found a short time after, having drunk two or three glasses of spirits. He was placed under restraint, and very soon after had an attack of acute mania. This lasted twenty-four hours.

After a week's convalescence he was about again as usual. The return of the next paroxysm was marked by the same mania, when restrained, of nearly the same intensity and duration.

He escaped on the return of the third paroxysm, and drank to stupor for two days, then was found and returned. The recovery was rapid, and later he was placed in the care of another physician. Here the same experience was repeated. The drink-paroxysm became a confused, trembling mania when restrained from procuring spirits; but if he could be intoxicated for a day or more, he would recover rapidly. Nothing less than profound stupor seemed to break up the mania.

This man possessed property, and the same question of responsibility came up. Like all others of this class, he had delusions of power to stop at will, and regarded his drinking as moral weakness and of little moment.

The following case came to me for consultation: A man in active business suffered from a heat-stroke and soon after became a periodic inebriate. These drink-periods were always preceded by states of unusual exhilaration, great buoyancy of spirits, self-confidence, and muscular activity. His wit and humor were overflowing and boisterous, then suddenly he would disappear and be found later stupidly intoxicated.

If any obstacles intervened he would spend large sums of money to procure spirits, seeking retirement where he could indulge unmolested. In a few days he would recover and go home, and after a short period of rest go out again as before.

These periods increased in frequency and duration, and the question of placing him under restraint when the premonitory mental exhilaration came on was proposed. He consented, and was placed in a private insane asylum. Two days after he had an attack of acute mania, and did not recover so as to go out for two months.

On the return of the next attack he went to a physician's house, where the mania reappeared with great severity.

At the next attack he ran away, and was stupidly intoxicated for four days, and then quickly recovered.

On the next occasion he was restrained in a hospital, had mania, ran away, became intoxicated, and while in this state lost large sums of money. The same question of responsibility, and what should be done, came up. To the advice to give up business and go under medical care, the objections were his apparent good health, and large business interests, which he conducted with pleasure and skill, and temperate life in every respect except at these periods. Occupation of both mind and body seemed essential to his health. To give up business and travel was especially dangerous, and to restrain him when these periods came on always developed mania. If allowed to drink to stupor for a time, other dangers appeared. In these drunken states he gave away large sums of money and signed notes.

The counsel of many eminent men has been sought, and still no solution has been reached.

In the future the narcotic action of alcohol will fail, then permanent mania will appear. When alcohol is withheld, mania comes on; when it is given, the mania is prevented.

These cases are unusual, but they outline many symptoms and conditions that are more or less common in all periodical cases of inebriety and dipsomania.

The drink-impulses in these periodical cases are states of mania seeking relief from some psychical pain or agony. This may be found in drugs as well as alcohol, and when ungratified manifests itself in complex mental symptoms of disorder and disease.

A clergyman who was a periodical inebriate, and was cured, has regularly every three months short periods of intense mental irritation. At these times he is angry at everything, is suspicious, and abuses his best friends. When this passes away he apologizes, and regrets his conduct keenly. He has not drunk any for four years. These periods last for three days or more, and are literally manias.

A professor in a medical college, who used alcohol to excess for years, and then abstained, has periods of two or three days' duration during which he is plunged into the deepest melancholy with the belief that he is going to die; hence gives up business for a time. Then suddenly the melancholy will pass away like a cloud, and he will laugh at his past fears and conduct.

These cases, which exhibit many phases of mental degeneration in distinct paroxysms, are common in persons who have drunk to excess and become abstainers. Are they caused by the drink-paroxysms of long ago? or are

they symptoms of other mental disease which have been aborted by the drink-impulse and exist as traces of other brain-disorder?

In some cases it is clear that the drink-impulse is another form of insanity, which from unknown causes develops in this way.

The very close relation which exists between these periodical drink-impulses and complex manias, and the alternation of one with the other, open new fields of research, which often have great practical interest. Thus in one case where the drink-impulse was preceded by melancholy, an important will was written that indicated incompetency, and was in the courts for years. This depended on the failure of the physicians to understand the mental condition of the victim.

Another case comes into court where a merchant kills a clerk for his efforts to prevent him from drinking. He was suffering from mania, which preceded or followed restraint from drink. A periodical inebriate made some business transaction which wrecked a large firm, and then developed the drink-impulse. The unusual character of this act, just before the drinking period, indicated mania and incompetency, but the court failed to recognize this. The family physician often recognizes states and conditions that are manias, pointing clearly to the irresponsibility of the person. When called to give testimony in court, he finds himself unsupported by any teachings of authority and hence fails to make his views clear.

The following conclusions may be stated as authoritative and fully sustained by all clinical study so far: The inebriate is in all cases, as a rule, insane, and of lessened capacity to reason and act normally. The periodic inebriate suffers from a marked mania, which may turn in any direction, taking on almost any form.

Careful study of the symptoms of these cases indicates the gravity of the brain-degeneration and the incapacity of the victim. It also points out the intimate association of periodical inebriety with insanity. The drink-impulse when gratified may prevent a more serious outbreak of insanity and permanent brain-lesion. The inebriety is often a symptom of brain-disease.

The responsibility and mental integrity of periodical inebriates should always be the subject of investigation, under all circumstances and conditions.

A New and Impervious Dressing.—Photoxylin, a substance in use among photographers, was recommended some time ago by Dr. Krysinski as a suitable material for mounting microscopic specimens, and more recently still it has been utilized by Professor Wahl, of St. Petersburg, as a substitute for collodion in surgical practice (*The Lancet*). A five per cent. solution in equal parts of alcohol and ether he finds preferable to collodion, as it adheres more firmly to the skin, not being so easily rubbed off in washing. It is absolutely impervious to liquids, and exerts a perfectly even compression on the tissues. In out-patient practice Professor Wahl finds that, after small operations, such as the extirpation of glands, the application of photoxylin solution enables him to dispense entirely with voluminous antiseptic dressings; also in plastic operations on the face, and in operations in the neighborhood of the male genital organs, such as those for the radical cure of hernia and castration, where it is very difficult to prevent the urine soaking through antiseptic dressings. Professor Wahl, after carefully arresting all hemorrhage, closes the wound with sutures and gelatine-plaster, and then covers the whole with a thin layer of wool soaked in a solution of photoxylin. This, it is stated, will remain eight or ten days, entirely resisting all the effects of moisture. Even in laparotomy, extensive dressings may, he believes, be dispensed with by painting a solution of photoxylin over the wound with a brush, or by the application of a layer of cotton-wool soaked in the same liquid.

PERSISTENT VOMITING OF LABOR ARRESTED BY TINCTURE OF IODINE.

By LLEWELLYN ELIOT, M.D.,

Assistant Physician Central Dispensary, Emergency Hospital, etc., Washington, D. C.

Gastric disturbance is one of the many unpleasant attendants upon the pregnant state, only a few women escaping entirely. Ordinarily the vomiting of pregnancy ceases in the earlier months, at times, to again appear toward the latter end of gestation. Now and again it is with difficulty subdued, and frequently abortion or premature labor has been induced for its relief. Dr. Thomas C. Smith,[1] of this city, has reported a case where abortion was performed for the relief of excessive vomiting in pregnancy. In this case the emaciation following the gastric disturbance was so great that the patient was a veritable living skeleton. Every remedy employed had failed, and as a last measure a bougie was passed into the uterus, thereby saving the life of the mother at the expense of the ovum.

Dr. John Blake White[2] has reported two cases of pernicious vomiting of pregnancy, occurring in the same subject, of which I make extracts: Mrs. M——, aged twenty-three, when the sixth month of utero-gestation was reached, had a slight "show," followed by slight uterine contractions and constant nausea, vomiting, and retching. The uterus was quieted, but the gastric symptoms continued unabated for ten days. Every well-known remedy for the relief of the symptoms was resorted to without any apparent benefit. That which seemed in any degree to be of service was carbolic acid, in fraction-drop doses, every half-hour or hour, *pro re nata*, and an occasional morphine suppository. The advisability of inducing premature labor was being considered when the stomach became more tolerant, and in due time convalescence was established. No further trouble occurred, and she was delivered naturally at term. During the period of her second pregnancy her condition continued favorable up to the sixth month of utero-gestation, when she was again sick with distressing nausea and vomiting, but recovered from the attack without any serious consequences, and continued in fair health up to within two weeks of her expected confinement, March 19th. He was called March 12th, when she had been suffering from nausea and occasional vomiting for several days. Her nausea and retching continued throughout the night, and these symptoms assumed a very serious aspect. On March 19th, when the patient's condition appeared to be rapidly becoming critical, and the induction of labor seemed to be decidedly the proper course to pursue, natural labor set in and resulted in a still-birth. The third stage was rapidly and satisfactorily accomplished; the womb afterward contracted firmly, and it was hoped that the persistent retching would cease after the seemingly exciting cause had been removed. The retching soon returned with increased energy, and, with the vomiting, continued, in spite of every means to control these symptoms, until evening, when the hemorrhagic character of the vomit became manifest. The symptoms persisted until death from asthenia supervened, twenty-four hours after confinement. There was no septicæmic influence to account for the malignancy of the symptoms.

Sometimes vomiting attends labor, but it causes trouble in but a few isolated cases, where, from its persistency, exhaustion becomes so great that the contractions of the uterus become too feeble to complete the labor. The cases recited show the little value attached to the remedies usually employed, and the benefit to be derived from the internal administration of tincture. According to the teaching of Wood, iodine, when taken internally in moderate doses, causes "some gastric uneasiness and a disagreeable metallic taste in the mouth; when larger

[1] Smith, Thomas C.: Amer. Jour. Obstet., June, 1886, vol. xix.
[2] White, John Blake: New York Med. Jour., August 7, 1886, vol. xliv., p. 154.

amounts are ingested, the gastric uneasiness may be intensified into violent vomiting, with increased salivary flow, abdominal pains, and sometimes purging."[1] He also states, in regard to the internal administration of iodine: "Nor should the tincture be given internally, because the iodine is precipitated by the watery juices of the stomach;"[2] but advises the use of the compound solution of iodine in doses of five to fifteen drops. The *rationale* of its action, in the class of cases to which reference is made, I do not attempt to explain; the fact remains the same nevertheless.

The United States Dispensatory[3] states: "The tincture of iodine is not elegible for internal use;" and further,[4] "the dose of the tincture is from five to fifteen drops, but Lugol's solution is a much preferable preparation for the internal administration of iodine."

Bartholow[5] states: "The vomiting of pregnancy can sometimes be greatly relieved by drop-doses, every hour or two, of the tincture."

Potter[6] writes: "But it is generally used as a local application or for injection into cavities;" and further,[7] "and in the vomiting of pregnancy drop-doses of the tincture every hour are often efficient."

Brunton[8] writes: "On account of its irritating action on the intestinal mucous membrane iodine is rarely given internally."

Farquharson[9] does not mention its internal use, nor does Gubb.[10]

The first recorded experience of the use of iodine in gastric disturbances which I have met with is by Dr. Thomas J. Gaunt,[11] who relates a series of successful experiences with the compound tincture, under the title of "The Use of Iodine as a Stomachic Sedative." He gave it in doses of from three to five drops. I have frequently obtained the same beneficial results which he reported, in cases of the morning-sickness of drunkards. If for any reason the compound tincture cannot readily be obtained, the simple tincture will answer equally as well.

M——, white, aged twenty-six, born in the District of Columbia, went into labor with her first child, March 2d, at 2 A.M. Her previous history was negative, if we except the usual vomiting attending the earlier months of her gestation. When called, at 3.30 A.M., the os was dilating, vagina moist, head presenting, membranes intact, but she was vomiting persistently. Previous to my arrival she had been given lime-water, pepsine, brandy, ingluvin, and cerium oxalate, without benefit. Mustard was ordered over the pit of the stomach, and cerium oxalate combined with ingluvin given without success. Carbolic acid in half-drop doses failed, as did lactopeptine. She was becoming rapidly exhausted and the pains had ceased. Whether to administer chloral hydrate per rectum, or to administer an anæsthetic and so terminate the labor, were questions to be weighed, when the iodine treatment came to mind. Following the advice of Dr. H. B. Hemenway,[12] in protracted labors—"Posture during Labor"—she was propped up in bed, hoping thereby to precipitate the labor, at the same time the finger being introduced and pressed against the anterior lip of the cervix; contractions of a feeble character followed, still the vomiting continued. At this juncture she was given five drops of tincture of iodine in a tablespoonful of sweetened water; the effect was magical, for the vomiting ceased almost immediately. To make assurance doubly sure she was given a second dose in thirty minutes. The labor now progressed rapidly, and at five o'clock, three hours after the first pains, she was delivered of a male child, well developed and healthy. Third stage normal. No bad effects followed the use of the iodine. While Dr. H. B. Hemenway is credited with the postural treatment of protracted labors, the idea was not new, as I have seen it mentioned briefly in obstetric works, but I think the credit of developing the idea belongs to him.

Dr. Samuel C. Busey,[1] of this city, read before the Medical Society of the District of Columbia, at a recent meeting, a paper on "Persistent Vomiting during Labor relieved by Anæsthesia." In this case success followed the use of the alcohol, chloroform, and ether mixture, but it was necessary to continue the administration to the end of labor, as the vomiting recurred upon the suspension of the anæsthetic. In the report of remarks made, it appears that "the tincture of iodine finally controlled the vomiting, but the pains ceased."[2] This is a mistake, as the labor progressed to a rapid end after the arrest of the vomiting, as appears above. Dr. L. Mackall[3] referred to the good effects of administering a cupful of crushed ice, swallowed as rapidly as possible; he had by this means allayed gastric irritability as well as promoted efficient uterine contractions, and prompt delivery in such cases.

The use of anæsthetics to lessen the pains in labor, I fancy, is a prolific cause of post-partum hemorrhage, since there is want of discretion and care in their use; but the first insensibility were the limit of their action they would be far safer. The safest plan is self-administration. The treatment here recited will be of service in cases of vomiting of pregnancy, that following a debauch, and almost any variety of vomiting, and as an agent so potent for good deserves a fair trial.

HERNIOTOMY UNDER COCAINE ANÆSTHESIA.

By W. W. HEWLETT, M.D.,

BABYLON, L. I.

A. D——, aged seventy-nine years and eight months, has long been afflicted with double inguinal hernia; the right developed over forty years ago, the left appeared twenty years after.

He has a weak heart and an intermittent and irregular pulse. He often suffers with œdema of the feet and distressing dyspnœa, for which he is obliged to resort to digitalis.

Owing to an ill-fitting truss, the hernia of the right side frequently descends, but he is generally able to reduce it without assistance. On August 13th it descended into the scrotum, and he was unable to put it back. On the 15th he summoned medical aid, but repeated taxis in various positions of the patient's body, with applications of ice, etc., utterly failed. Stercoraceous vomiting and strangulation of the gut ensued, and it soon became apparent that death must speedily follow unless resort was had to surgical means. The advanced age of the patient and the serious condition of his circulatory system rendered it extremely hazardous to administer ether or chloroform. It was decided therefore to perform the operation with the aid of cocaine.

On August 19th I injected two drachms of a four per cent. solution of cocaine in sixteen different places, seven subcutaneously on either side of a line where the incision was to be made, and two deeper and near the neck of the sac.

After fifteen minutes the operation was performed, under antiseptic precautions, in the usual manner, with the assistance of Dr. E. C. Wendt, of New York; Dr. S. R. Corwith, of Islip; and Dr. A. B. Leggatt, of Babylon. The stricture being in the neck of the sac, the latter was opened and the intestine, though deeply congested and purple in color, was returned into the abdominal cavity. The patient was perfectly conscious and a very interested observer during the entire operation. He de-

cleared that he felt no pain from the knife, and that we did not hurt him except when the tumor was pushed backward. When he saw the distended intestine rising before his gaze, he said: "Are you going to tear me all to pieces?"

There was no shock. Free spontaneous dejections occurred during the night. The wound closed by primary union, and his progress toward recovery has been uninterrupted. One week after the operation he sat up on the side of his bed and shaved himself.

So far as I can ascertain, this is the first recorded instance of the performance of herniotomy under cocaine. The result fully demonstrated to the gentlemen who kindly assisted in the operation, and also to me, that the employment of cocaine in cases like the one here described is both feasible and highly satisfactory.

Clinical Department.

RELIEF OF AN ACUTE INTESTINAL OBSTRUCTION BY PUNCTURE WITH A TROCAR.

Dr. M. R. Perry, of Russellville, Ky., reports the following case: "Mrs. P——, thirty-five years of age, partook freely one day of a fruit lunch, consisting of bananas, pineapples, and blackberries. A few hours after a severe pain began in the region of the ileo-cæcal valve, which gradually increased in violence until the next day, when I was called. She is of a constipated habit, and subject to occasional attacks of colic. I found the abdomen somewhat swollen and tympanitic, with great tenderness in the region of the valve. I gave at once a hypodermic injection of one-sixth of a grain of sulphate of morphine, which was repeated three times within an hour before there was any relief. In the evening ten grains of calomel was given, and in six hours one ounce of castor-oil, with no effect. On the following day the hypodermics were administered every four or five hours, the dose being increased to one-fourth of a grain. There was great distention of the abdomen, with nausea and occasional vomiting; the patient was very restless, throwing herself from side to side of the bed every few minutes. On the day after this the morphine was increased to one-half grain; the pain was intense, the distention was increasing, there were distressing nausea and vomiting, but no movement from the bowels, though enemas and purgatives were freely administered. The next day the symptoms were about the same, except increased pain and restlessness, requiring one grain of morphine three or four times in the twenty-four hours to give any rest. Twenty-four hours later, at my request, Dr. R. H. Keene was called in consultation, and, after a careful examination, agreed to the diagnosis of obstruction at the ileo-cæcal valve, with fecal impaction and inflammation. The next day Dr. Keene suggested the administration of two drops of croton-oil, which was repeated in three hours, with no effect. A long rectal tube was then pushed up the bowel with a female catheter alongside, and more than a gallon of warm water thrown up; this was tried several times during this and the following day, with no result. On the morning of the eighth day the symptoms became still more grave, the distention was so much increased as to interfere with the movements of the diaphragm, the nausea was very distressing, and fecal vomiting occurred. I suggested to Dr. Keene the great danger of any further delay if we intended any kind of operative measure; he readily concurred, and said our patient could not live twelve hours longer with the rapidly increasing distention of the abdomen. I at once introduced a large aspirator-needle in the median line about two inches below the navel, and this permitted the escape of a large quantity of gas. A trocar was then passed through the abdominal wall in the right iliac region, about two inches above the ileum, into the gut; this was allowed to remain for three or four hours, during which time considerable quantities of gas, with about one quart of liquid fecal matter, escaped. In eight hours after the introduction of the trocar there were two large evacuations from the bowels. The nausea and vomiting were relieved as if by magic, the distention very much reduced, and, in fact, all the symptoms were much better in the following thirty-six hours. For three days after the operation there were from six to ten large serous evacuations, indicating inflammation of the mucous lining. Enormous quantities of morphine and opium were used before and after the operation, in order to relieve pain and subdue the great restlessness. On the twentieth day after the operation the patient was entirely out of danger, all the symptoms of a grave nature having disappeared. At this time she is able to be about her room, it still being necessary to administer one-tenth of a grain of morphine daily. Frederick Treves gives several cases of intestinal obstruction that were cured by this procedure, in some of which it was resorted to as a mere palliative. It strikes me that in those cases of fecal impaction, or inflammation, in and about the ileo-cæcal valve, this operation should be tried before resort is had to one of greater danger. I have never read of a similar case relieved by the same method in any of the American journals."

IODISM IN THE NURSING INFANT.

Dr. Henry Koplik, of New York City, writes: "The rarity of recorded cases of iodism in the nursing infant during the administration of the iodide of potassium to the mother has induced the writer to publish the following: Traces of various drugs have been found in the milk of the nursing women a short time after ingestion. Some investigators (Spaeth and Schoenstein) have endeavored to solve the problem of therapy of the nursling through the milk of the mother (Fleischman). This would be of especial utility in relation to the subject of congenital syphilis. Rhubarb, potassium sulphide, potassium iodide, iodine, and solutions of opium (Fleischman) have all been found in the mother's milk after their ingestion by her. Iodide of potassium has been found quite frequently in mothers' milk, and even in the urine of the nursing child (Ringer, Bartholow). Cases of drug-eruption recorded from the iodides in the infant are rare, for the reason that in these little patients the eruption may so easily be mistaken and taken for other cutaneous and transient affections so common to children.

"Mrs. X——, aged thirty, Irish extraction, mother of two children; youngest three months; no abortions; under treatment at my polyclinic for indurated anal fold, condylome of the anus, and fissures of the anus (syphilis). The child at the beginning of treatment was aged three months, nursing at breast; its skin, mouth, nose, anus, vulva all free from any eruption or signs of syphilis. The mother, outside of a few cicatrices of a suspicious character around the vulva, showed no other accident of syphilis; the breasts healthy, of good development, and secreting abundance of good milk. The child was normal in development and of healthy appearance. The patient (mother) was, in addition to local treatment, put upon potassium iodide (℥ iiss.–aq. ℥ ij.), ℥ j., t.i.d. in water internally. Two days after having taken the iodide the mother brought the child to the dispensary, and showed me some few macules and papules on the right arm and on the forehead, of a rose-red color. Within two days these were reinforced by others on the chin and upper part of the chest and abdomen. The old spots had developed minute pustules. There were some looseness in the bowels and some dyspeptic symptoms, and a little increased secretion in the nose. The iodide was reduced to one-half. The patient returned in two weeks; she had not been taking the iodide for about ten days, and the eruption on the child had disappeared. The iodide was commenced

again, and in four days the patient not only showed the eruption on her face of maculo-papules again, but in the milk traces of the iodide were found, and on the child the eruption above described appeared again on the hands and face, but less intense, and not with such clear dyspeptic symptoms. There was no fever. The infant seemed tolerant of the drug to a greater extent than on the first trial."

A CASE OF DOUBLE COMPOUND FRACTURE.

Dr. J. Leon White, of Halsey Valley, N. J., writes: "In The Medical Record of July 16th, Dr. R. C. Newton, in his article on 'Compound Gunshot Fractures,' speaks of the rarity of cases recorded of double injuries of this kind, and says that a search through the principal medical journals for the last eighteen years reveals but two cases of double compound fracture reported since the war, only one of which was a gunshot wound. I am able to add one more case of double compound fracture, though not gunshot wounds. The case was seen by me in the autumn of 1877, while a student. My preceptor, Dr. A. Treganowan, of South Amboy, N. J., was called in consultation and I accompanied him. The patient was a German, about fourteen years of age, and had received his injuries by falling from a tree while nutting. Besides lesser injuries he sustained a compound fracture of both forearms. In one arm both bones were involved, and in the other the radius, certainly—but I cannot say positively that the ulna was, my impression being that this bone was also fractured. The broken ends of the upper segments, in both arms, protruded for at least an inch from the wounds, each being about two and a half inches above the wrist-joint. Three days after, one arm, I think, was amputated at the juncture of the middle with the upper third of the humerus, for rapidly spreading gangrene. The other arm did well, and the patient made a rapid recovery, becoming, as I have repeatedly noticed to be the case after amputation of a limb, much more fleshy than before receiving his injury."

PELVIC ABSCESS AND UTERINE CYSTS.

Dr. F. L. Smith, of Shaftsbury, Mich., reports the following case: "Mrs. Myrtie B. W——, aged nineteen, married three and one-half months, presents the following history: When about thirteen years of age she was blind for several months, but the sight was restored by an operation the nature of which is unknown. Had always been irregular in her monthly periods, the periods occurring sometimes twice a month, sometimes once in two or three months. She had been treated three times for lung troubles. During the winter of 1885–86, was treated for an abscess in her right side (pelvic, as she would point to it). Has had what were said to be three miscarriages since April, the last one on August 4th, having skipped her July period. At this time she flooded profusely. Felt well on August 5th, but began to show signs of inflammation on August 6th, and grew rapidly worse until the 8th, when she died. In this sickness was attended by an irregular physician. The nurse said that a fœtus one and a half inch long, and nearly perfectly formed, came away. By invitation of the friends I was present at the post-mortem examination, twenty-four hours after death, Dr. T. A. Kay operating, and the following points were noticed: Body thin, rigor mortis marked, abdomen slightly enlarged and hard. There were some dark inflammatory nodules in the vagina. There were evidences of a slight general peritonitis. The uterus presented first and was mistaken for the bladder. On puncture, to empty it of its contents, an amber-colored fluid flowed out, the inside of the walls being covered by an amber-colored, jelly-like substance, which was found to be encysted. The entire muscular structure was displaced by these cysts, which varied in size from a pea to an egg. The entire uterus weighed ten or twelve ounces. There were no traces of a cervix, the vagina ending in a pouch in the fundus uteri. The intestines, great omentum, uterus, and appendages were glued together by old inflammatory adhesions. Only the right ovary could be found, it was natural in size and somewhat inflamed. Between the ovary and uterus an encysted pus-cavity was found, containing five or six ounces of greenish black pus. The sigmoid flexure was nearly surrounded by the cyst-like wall of the uterus. Kidneys were normal. Spleen slightly enlarged. Lungs normal. The heart, normal in appearance, contained a clot three inches in length which was adherent just within the tricuspid valves. This was probably the cause of death. During life the patient never had any peritonitis—in death she presented no appearance of lung trouble." Dr. Smith asks whether the abscess that was found could have been the one the patient was treated for in the winter of 1885–86, and he asks also for any information concerning the literature bearing on this condition.

VARICOSE VEINS ABNORMALLY LOCATED.

Dr. George Ross, of Richmond, Va., writes: "An uncommon case has just fallen under my observation—so uncommon that I fail to find its duplicate in any work on surgery accessible to me. The subject is a young man, for ten years past a watchman at the railroad wharf near this city. In the first year of his employment he fell through the hatchway, a distance of twenty feet, lighting on his feet. If soreness be excepted, no immediate effects followed. Later on within the year he noticed a swelling over the pubis, steadily growing but not interfering with his duties. For several years it has remained practically stationary, and to casual inspection would give the impression of a double inguinal hernia. When the man is standing, the mass is like a pendulous apron, which, on examination, is found to be an enormous knot of 'varicose veins,' covering the entire super-pubic region. Many of the veins are as large as the human thumb, and all empty themselves when the patient lies down. He declares himself equal to any work or play engaged in by his companions, and is now filling an appointment on the police force of the city."

A RARE CONGENITAL DEFORMITY.

Dr. E. H. Martin, of Salisbury, Vt., reports the following case: "Mrs. P——, living in this vicinity, was delivered, after an easy labor, on April 2d last, of a female child weighing about eleven pounds. This child presents the anomaly of either complete absence or complete fissure of the sternum. There is a breach of about two inches in the continuity of the bony thoracic wall, in the space usually occupied by the sternum, in its whole extent. The clavicle and ribs articulate with the ribs of the same side, but have no bony or cartilaginous connection whatever with their fellows of the opposite side. This space of bony deficiency is covered only by soft structures, which with every act of inspiration and expiration flap inward and outward. The heart, every pulsation of which can plainly be seen, lies within this space, and can be readily grasped through its thin covering by the thumb and finger. There is a space about as large as a nickel where the integument over the heart has attained so great tenuity as to be almost transparent, and presents a silvery-white appearance. There is a similar deficiency in the abdominal wall, the recti abdominis being separated or non-developed, and there is an umbilical hernia which, in acts of straining, protrudes as large as the clinched fist. The convolutions of the small intestine can be readily seen through their thin covering. The child is still living at this writing (four and a half months), and has developed an inguinal hernia of the right side. The pubic bone and pudenda are normal. Weight about same as at birth. Parents healthy, and their older children, several in number, present no anomaly."

Progress of Medical Science.

A New Method of Treating Localized Tubercular Processes. — The Vienna correspondent of the *British Medical Journal* writes as follows on this subject: "In a preliminary communication recently made by Dr. Kolischer to the Imperial Royal Society of Physicians of Vienna, he gave an account of the results which he had obtained in the treatment of localized tubercular affections by parenchymatous injections of a solution of phosphate of lime. The following considerations induced him to make a trial of this method. He wished to ascertain whether localized tubercular processes could not be cured in a way analogous to that in which spontaneous recovery takes place in pulmonary tuberculosis, namely, by supplying the diseased organ with lime salts, and thus artificially producing calcification of the fungous masses. Then, bearing in mind the fact that the inflammation set up in cases of articular fractures sometimes checked the tubercular process, he was led to suppose that an artificial inflammatory irritation might accelerate the cure of the tubercular disease. He used concentrated solutions of phosphate of lime for the parenchymatous injections. Healing of the fungous masses was obtained by this method, in the *clinique* of Professor Albert, in from four to six weeks. The injection was followed by severe reaction; the fungous masses broke down, and healed very rapidly. The process reminded one of the demarcation of gangrene. The florid healthy granulations which appeared after the fungous masses had been cast off filled the cavities after an interval of fourteen days. When a necrosed piece of bone was present in a fungosity, this quickly broke down, and the bone was eliminated with a rapidity which could only be attributed to the treatment. The effect of the treatment was also seen in cases of fungous processes with enlarged lymphatic glands. In a case of fungoid disease of the female breast, the swelling of the glands also disappeared after the injections, and this was still more evident in a case of necrosed bone in which the axillary lymphatic glands and those of the bicipital groove were enormously enlarged. Dr. Kolischer showed some patients who had been affected with tuberculosis of the joints, and successfully treated in the way described. The first case was that of a girl, who had tubercular disease of the elbow-joint, for which she had been admitted in January. The joint was at that time anchylosed in the rectangular position, and the skin over the affected part was very tender, especially over the outer condyle. The olecranon could not be felt. After the injections, a period of reaction with fever and pain was first observed. This was followed by a period of induration. Three weeks later complete absorption had taken place, and the joint had almost recovered its normal mobility. These successive stages of reaction, solidification of the masses, absorption and speedy recovery of the function of the joint were also noticed in a second case. Dr. Kolischer, moreover, showed a case of caries of the hand in a child, aged six, and a case of tubercular disease of the knee-joint, both of which had been successfully treated in the same way. He also presented a case of calcified caries of the hand in an adult, a cured fungosity of the tibio-tarsal joint, in which there was circumscribed necrosis of the fascia, and, lastly, a case of anal fistula, which had not been scraped with the sharp spoon, but only slit up, and packed with gauze saturated with the above-mentioned solution. At the time this patient was shown, fourteen days after the application, healthy granulations could already be seen, and the wound was beginning to skin over. In his earlier experiments Dr. Kolischer had used a solution of chlorate of lime for the parenchymatous injections. This, however, was found to produce such severe reaction that afterward he, at the suggestion of Dr. Freund, employed only solutions of phosphate of lime, in which there was always an excess of phosphoric acid. Dr. Kolischer concluded by saying that he hoped to be able to report next to the society on the results obtained in the treatment of tubercular affections of the larynx and pulmonary phthisis by the same method. Professor Albert, in whose *clinique* the experiments had been performed, said that he wished to draw the attention of the profession to the good results which had been obtained by Dr. Kolischer; he would most urgently recommend further trial of the method. Few facts had made such an impression on him as those just related by Dr. Kolischer. At first he (Professor Albert) had taken up a skeptical attitude, but the results had surprised him. He had, indeed, seen good results in tubercular disease from igni-puncture, but in Dr. Kolischer's cases free mobility of the joints was obtained, an advantage which could not be overrated. We had to deal here with new and most remarkable facts."

Mesenteric Cysts.—Dr. E. Hahn recently read a paper on Mesenteric Cysts before the Berliner Medizinische Gesellschaft. These cysts are rare. Victor Angagneur is the only writer who has written a good monograph on the subject. The mesentery consists of connective tissue, adipose tissue, lymphatic and blood-vessels, and glands (*British Medical Journal*, June 18, 1887). From the connective tissue and fat, fibromata, lipomata, enchondromata, sarcomata, myomata, and cysts may be developed. Carcinomata and dermoid cysts have not been discovered in the mesentery. Rokitansky and Virchow both believed that mesenteric cysts were developed from degenerated glands. Hahn divides mesenteric cysts into (1) blood-cysts, (2) chyle-cysts, (3) serous cysts, and (4) hydatid cysts. According to Angagneur, 90 mesenteric tumors have been observed, of which one-third were cystic. Of these, 17 were subjected to operative measures. In 5 cases of chyle-cysts, abdominal section was performed; in 3 of these cases the cyst was removed, with 1 death; in 2 the cyst was incised and drained, the patient recovering. The fluid, sometimes abundant, is milky, and contains fat and albumen. The cyst-wall is composed of connective tissue, with traces of lymphatic tissue, and is not lined with epithelium. Millard and Tilland and Werth have supplied good evidence that these cysts arise from lymphatic glands. Blood-cysts of the mesentery are very uncommon. Dr. Hahn states that two cases have been carefully noted—one occurred in Sir Spencer Wells' practice, the second was operated upon by Hahn himself. The patient was a girl, aged eight. Two years before operation a swelling, the size of a hen's egg, was discovered in the abdomen; it was attributed to a blow. The swelling was freely movable, and at first caused little inconvenience, but at length became the source of severe pain, much like that which is felt in some cases of floating kidney. The child would be cheerful for a time, and then complain of intense pain, and lie down with the thighs flexed, and the head bent till it nearly touched the knee. This pain would last for two or three days and nights, preventing sleep. An incision over four inches in length was made through the linea alba, the great omentum was pushed aside, and the dull-red, lustreless surface of the tumor was exposed. The incision was enlarged, and the tumor could then be easily raised. A coil of intestine formed a frill in front of the growth. The anterior layer of mesentery was divided, the fluid contents of the cyst emptied, and the collapsed cyst was then dissected away. After checking the hemorrhage the operator sewed up the wound in the mesentery with catgut. The child made a rapid recovery. Serous cysts are the most frequent and the most serious form of cystic disease of the mesentery. They often become very large. Simple tapping has seldom caused a serous mesenteric cyst to disappear. Extirpation has been attempted five times, with three deaths. It appears that incision and drainage are preferable to complete removal of the cyst. Hydatid cysts have only been twice noted in literature. A discussion followed the reading of Dr. Hahn's

paper. Dr. Gottschalk described a case of serous mesenteric cyst successfully removed by Dr. Landau. The pedicle, formed out of the mesentery, was returned, and drainage was not found necessary. Dr. Gottschalk preferred complete operations to incision and drainage, and in this opinion most British operators will agree with him. Dr. Küster had observed one chyle-cyst and one hydatid cyst of the mesentery. There was generally great difficulty in emptying the cyst, which was enveloped in the folds of the mesentery, the intestine being often stretched over the tumor. He believed that total extirpation was dangerous and unadvisable, incision and drainage answering very well. Dr. Hahn replied that in the case of chyle-cysts and blood-cysts not one death had followed extirpation.

Boracic Acid in the Treatment of Leucorrhœa.—From the excellent results which are yielded by boracic-acid packing in chronic suppurating otitis, Dr. N. F. Schwartz (*St. Louis Courier of Medicine*) was led to employ it in a case of leucorrhœa which had resisted the most persevering use of the ordinary remedies. The experiment was successful within a fortnight, and the patient has remained well for several months since. Dr. Schwartz states that he has been equally successful in a number of other cases. His manner of using it is as follows: Having first irrigated the vagina with water at as high a temperature as can well be borne by patient, a cylindrical speculum is introduced, and the vaginal walls very carefully dried, first with a soft sponge and then with absorbent cotton. This done, boracic acid in crystals is poured into the mouth of the speculum and pushed up against the uterus and vault of the vagina with a clean cork caught in a uterine sponge-carrier, sufficient acid being used to surround and bury the intravaginal portion of cervix, filling the upper part of vagina. A tampon of absorbent cotton is then firmly pressed against the packing, and held *in situ* until the folds of the vaginal walls close over it as the speculum is withdrawn. This should be allowed to remain three or four days, or even longer, as after this time there still remain some undissolved particles of the acid, nor will the tampon seem at all offensive. The ostium vaginæ, if examined in twenty-four hours, instead of being besmeared with the leuchorrœal secretion or discharge, presents a clean appearance, and is bathed in a watery fluid, which begins to appear several hours after the packing has been placed; and in his cases this was the only discharge noticed afterward. However, a second or even a third repetition may be necessary, but in none of his cases, numbering nearly a score, has he found more than a second packing called for, and in many one sufficed; and in no instance has its use occasioned pain, nor even inconvenience.

Lesions of the Placenta in Albuminuria.—Albuminuria has long been recognized as predisposing to puerperal hemorrhage; and in women, who have succumbed to attacks of eclampsia, hemorrhages have been found in the brain, liver, kidneys, and lungs. The placental lesions, however, had so far escaped notice. According to Dr. Rouhaud (*Archives de Tocologie*), the outside appearance of placentas containing hemorrhagic foci is not, as a rule, different from the normal, except they, or some of them, should be near the surface. On manipulating the placenta indurated nodules can be felt, on cutting into which a clot of variable size may be discovered. In the first variety the cavity is irregular, ragged, and throws out branches, never, however, communicating with the surface. In a second variety the blood is contained in cavities, round or oval in shape. The walls of these cavities are formed by the tissue of the placental cotyledons, and no trace has ever been found of the orifices of the vessels, the rupture of which had given rise to the hemorrhage. They are generally situated near the borders of the placenta. Their number varies from four to fourteen, but does not often exceed four or five. Out of sixty-eight women whose urine contained albumen during labor, twenty-eight had more or less hemorrhage into the placenta, equal to forty per cent. of the cases. The frequency would appear to bear some relation to the intensity of the albuminuria. Twenty out of the twenty-nine cases in which hemorrhages were found were primiparæ. The diagnosis cannot be made with certainty. A sensation of sudden weight and pain in the pelvis toward the termination of pregnancy, with albuminuria and slowing of the fœtal heart, may give rise to a suspicion, but rarely with sufficient clearness to justify intervention on behalf of the fœtus. Albuminuria alone would not seem to have an unfavorable effect on the progress of pregnancy, but placental apoplexy is very apt to cause abortion. In twenty-nine cases of albuminuria with hemorrhage into the placenta, pregnancy went on to term fourteen times; in the remainder delivery was premature, most usually between the seventh and eighth month. Out of forty-one cases of albuminuria without placental lesions, premature delivery took place seventeen times; but in six of these, hydramnios, or twins, may have conduced to this result. Albuminuria without placental lesions would therefore appear to cause premature delivery in twenty-five per cent. of the cases. As regards the health of the fœtus, the result of placental hemorrhage is even more disastrous. In twenty-nine cases of albuminuria with placental lesions, in eleven the fœtus was still-born, and the remainder were much below the usual weight. Out of forty-five children born of albuminuric women without placental lesions, twelve only were still-born, and the others were of normal weight.

The Distribution of Pyæmic Abscesses.—At a recent meeting of the Cambridge Medical Society (*British Medical Journal*, July 30, 1887), Mr. Stephen Paget read a paper on the Distribution of Pyæmic Abscesses. If cases of pyæmia were arranged according to the nature of the primary lesion in each case, it would be seen that there was some evidence of a relation between the situation or character of the primary lesion and the situation of the secondary lesions. In pyæmia after venesection, effusions into the serous and synovial cavities were very frequent, while the kidneys and the spleen were seldom affected. In pyæmia after amputation the spleen and the liver were affected in a certain number of cases, but effusions into the serous cavities were much less frequent than in pyæmia after venesection. Effusions into the joints were also less frequent. The heart was often diseased in pyæmia after acute necrosis, and the spleen was not infrequently affected. Effusions into the pleuræ were common; so were effusions into the joints, but usually it was the elbow-joints that suffered; the knees did not appear to have suffered in any case, except by extension of inflammation from the femur or the tibia. Thus the kidneys were affected in none of the venesections, and in only two per cent. of the amputations of the thigh, but in sixty-six per cent. of the cases of acute necrosis. The heart was affected in only five per cent. of the venesections, and in none of the amputations, but in sixty-seven per cent. of the acute necrosis cases. The liver was attacked in five per cent. of the venesections, six per cent. of the necrosis cases, and twenty-one per cent. of the amputations. The spleen was attacked in none of the venesections, but in 16.5 per cent. of the amputations, and in twenty per cent. of the necrosis cases.

How to Open a Felon.—Dr. John Ashhurst, Jr., says that in opening a felon the parts to be avoided are lines of the arteries and that of the flexor tendon, which is the median line. The felon should be opened midway between the artery and tendon. If necessary, it can be opened on both sides. If the sheath of the tendon is opened, the tendon will almost always slough, and the finger will be useless.—*Polyclinic.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, September 24, 1887.

LEGAL'S DISEASE.

UNDER this title Dr. Pietro Masucci describes, in the *Giornale Internazionale delle Scienze Mediche*, No. 6, 1887, an affection characterized by severe and persistent temporo-occipital neuralgia, which is intimately associated with, if not entirely dependent upon, chronic follicular pharyngitis and inflammation of the middle ear. In this article the author states that many years ago he had observed a number of cases of chronic cephalalgia, accompanied by inflammation of the naso-pharynx and tympanum, in which the first-mentioned symptoms disappeared entirely upon improvement in the local conditions consequent upon appropriate treatment. He had at the time made notes of these cases, and, when opportunity offered, scanned the current literature to learn whether similar observations had been made by others. No description of any affection similar to those observed by him appeared until Legal published his series of thirty cases in the *Deutscher Archiv für klinische Medicin*, No. 2, 1887. The author's description of these cases corresponded exactly in all essential particulars to those observed by Masucci.

The disease may best be described by a brief recital of one of the cases observed by Masucci. A young man, aged nineteen, came under treatment, complaining of severe paroxysmal occipital neuralgia. There was marked hyperæsthesia in the left temporal region, the slightest pressure on this part causing the most intense pain. There was also considerable dryness of the throat, and the patient complained of some deafness. Examination showed chronic granular pharyngitis, with secondary catarrhal trouble of the Eustachian tubes, chronic bilateral rhinitis, and hyperæmia of the drum-membrane. Treatment was directed solely to the cure of the local lesions, no remedies being given for the relief of the cephalalgia, despite the urgent entreaties of the patient. The good effects of this treatment became manifest within a few days, and as the catarrhal trouble progressed toward recovery, the neuralgia and temporal hyperæsthesia gradually disappeared. The result was most satisfactory, and the patient made an excellent recovery.

The author admits his inability to explain the exact relation between the local lesion and the neuralgic trouble. It would naturally be supposed that the deflection of the drum-membrane, owing to the rarefaction of the air in the tympanum, might cause some irritation in the nervous filaments ramifying on this membrane, which filaments are derived in part from the auriculo-temporal nerve. The experiments of Legal, however, have shown that the drum-membrane may be strongly deflected artificially without giving rise to any nervous disturbance of this nature. But however the neuralgia might be cured, its dependence upon the local trouble was clearly shown by the results of treatment.

The author insists upon the necessity of recognizing the possibility of a persistent paroxysmal temporo-occipital neuralgia, arising from a chronic inflammation of the naso-pharynx, with secondary extension to the Eustachian tube and tympanic cavity. And he concludes his interesting memoir with the advice of Legal. The latter says that whenever a patient presents himself complaining of persistent cephalalgia, with hyperæsthesia over the region of distribution of the temporo-occipital nerve, an examination of the pharynx and ear should be made, and insufflations of compressed air should be practised. If then, after these insufflations, a sensible diminution in the pain, either spontaneous or short, due to pressure, be experienced, the physician may hope to obtain, in many if not the majority of cases, a complete cure of the headache. This is to be effected by means of appropriate treatment directed to the relief of the inflammation of the naso-pharynx and Eustachian tubes.

MUSCULAR ATROPHY RESULTING FROM THE PROLONGED APPLICATION OF BLISTERS TO THE ARM.

THERE is a warning contained in a communication made by Dr. Collignon in the *Journal de Médecine et de Chirurgie Pratiques* for August, 1887, which is well worthy of consideration. The writer states that, when he was five years old, he suffered from a rebellious kerato-conjunctivitis following scarlatina. Other means of relief having proved ineffectual, the physician advised the application of large blisters to the arms. These were made, and were not allowed to heal for a period of eighteen months. The result of this was an atrophy of the muscles of both arms. The writer is otherwise of fair physical development, but the muscles of the upper extremities, between the shoulders and the elbows, are small in size and weak as compared with those of other parts. This is an instructive case, and one that may with profit be remembered. For the well-meant advice of a short-sighted physician has resulted in an injury which time has been unable to repair.

TREATMENT OF SCIATICA BY REFRIGERATION OF THE SOUND LIMB.

SOME time ago M. Debove announced that he had been able to afford marked relief in a case of obstinate sciatica by means of a spray of chloride of methyl applied along the course of the sciatic nerve in the unaffected member. At a recent meeting of the Société de Biologie (*Le Concours Médical*, August 6, 1887), M. Raymond reported that he had obtained favorable results by a similar method in three cases. He found, however, that the effect was the same even when the spray was directed to any part of the limb, and not necessarily along the course of the sciatic nerve. This would seem to prove that the relief of the pain was due to an impression made upon the spinal

centres by refrigeration of the peripheral nerve-terminations, rather than to a direct influence exerted upon the trunk of the affected nerve itself, or of its fellow in the opposite limb.

A LITTLE GIRL'S INVESTIGATION OF PRELIMINARY MEDICAL EDUCATION.

Dr. Frederick H. Gerrish, of Maine, has been making some unique investigations into the requirements, as to preliminary education, called for by the medical colleges of this country. He made his inquiries through the agency of an eight-year-old girl, whose handwriting gave plain evidence of her immaturity. She made written application for admission to the various colleges under an assumed name, and in each application confessed her absolute ignorance of some special study, proficiency in which is supposed to be necessary to a comprehension of medical science.

About one-half of the answers—according to the *New York Times*, which notices the matter editorially—received by the child, informed her that she could not enter the course prescribed until she was able to pass the preliminary examination, including the studies in which she had confessed her ignorance. The other half, however, evinced a willingness to take the fee of the applicant, and promised to make a doctor of her in spite of her confessed inability to pass the examination prescribed in their prospectuses as necessary to gain admission to their halls. Dr. Gerrish read specimens of some of these answers. One college wrote encouragingly: "Our examination is not difficult; no one has yet failed to pass." Another kindly wrote: "Natural philosophy is not required, except as a suggestion in the line of a liberal education." A third, bent on quieting all anxiety on the part of the applicant, wrote: "The preliminary examinations are not difficult, and no deserving applicant is rejected on account of not being able to pass them. Call and see me when you are in the city, and I will fix it so you can enter."

Dr. Gerrish's investigations tell us nothing new, but they emphasize in a striking way the melancholy condition of medical education in many parts of this country. Some improvement is, we believe, slowly, very slowly, taking place; and the American Academy of Medicine, before which Dr. Gerrish's paper was read, is doing good service in keeping the need of reform steadily before the profession.

ECHOES OF THE CONGRESS.

When the late Medical Congress was in session, the editors-in-chief of our various leading dailies gave out their orders to "write it up." So next morning there duly appeared a half-column or more of reflections upon the great triennial event. We have been looking over these various efforts of journalistic skill with much interest. On the whole, they are creditable to the editorial capacity of the daily press. We do not find the matter treated with the copiousness of a Macaulay, or the cumulative vigor of a Carlyle, but the proper things, as a rule, were said in an agreeable manner. We recognized the conventional compliment that medicine is a noble profession, and noted a considerable iteration of the obvious comment, that the meeting of so many physicians must prove beneficial to humanity, and incremental to human knowledge. We found that medical science was criticised as inexact, medical art as of limited power, and medical practitioners as a somewhat quarrelsome and bigoted, but (in another paragraph) learned and intellectual class. One contemporary suggests that a pleasant address and plenty of assurance are half the battle; but another describes the life of the physician as one of incessant and self-sacrificing toil.

Few journals had much to say as to the success or lack of success of the Congress, although one prominent Philadelphia paper affirms that "it is notorious that the Washington Congress was not such a success as it should have been, or as it certainly would have been, had not many of the most eminent medical men in the United States refused to have anything to do with it."

The cause of the trouble it attributes to "the code of ethics," an explanation which bears with some severity on our Philadelphia brethren, who believe in the code with an intensity inversely proportional to their enthusiasm for the Congress.

Although such apt and interesting generalities as above indicated were published, the numerous and prolonged sessions do not seem to have struck any sparks of original and fructifying power in the contemporary press. One paper, however, dwells with force and appositeness upon the lack of means for scientific research in this country, and suggests the need of a great medical university where the medical sciences can be studied for themselves alone. If the Congress could awaken our citizens to an appreciation of this need, its meeting would be truly of incalculable benefit.

TEMPERANCE INSTRUCTION IN SCHOOLS.

Probably no class of men in the community are better fitted to give a calm, unprejudiced opinion on the alcohol question than physicians. In their capacity of public sanitary guardians, they feel an interest in all practical measures designed to limit the deleterious effects of the use of liquors upon the human system. The latest effort in this direction is the introduction into the public schools of several States of so-called "temperance" text-books and other paraphernalia of teaching. Some communities have already experienced the first-fruits of this new system of instruction. These results are somewhat curious. It is found that the incidental facts designed only to lead up to the one great moral are more prominent in the pupils' minds than the moral itself. The various charts which portray stomachs, livers, and other viscera diseased from alcohol are regarded much in the light of picture-books on a large scale. They produce no more impression on a child's mind than the sight of a tattooed man, or some "freak" of a dime museum.

It is right that the question of temperance should be brought down to the scope of a child's ideas; right from a medical stand-point as well as from a moral one. But it is hardly the judicious course to teach him to regard alcohol as a deadly poison under every circumstance. He will be disillusioned as he grows older and will look back to his text-book teaching as a mass of overstated facts. The trouble with many of the text-books on temperance used in schools is that they are not physiologically cor

rect. They are written by persons with more zeal than accurate knowledge, and consequently we have sometimes ludicrous statements from pupils. The description of the distillation of alcohol strikes the child as a very interesting thing, and so the fact designed to be taught—its pernicious effects—fails to make a lasting impression.

We think that a better state of things could be brought about if physicians could be led to take a more active management in the public schools. Ministers, lawyers, business men, and professional politicians are always represented upon school-boards, but rarely physicians. They are the very ones who should be fully represented. They can, by their advice, better than any other class, conduce to bring up a class of pupils who shall have sound minds in sound bodies. They can prevent the introduction of text-books on temperance or any other topic having reference to physical matters which are not written with a due regard for truth and for the receptivity of the minds which are to grasp it. It is coming more and more to be realized that a physician's duty to the community oversteps the sphere of mere sanitary matters and lays hold upon social factors as well. Much of the teaching in schools nowadays is one-sided, because the mind is regarded as something apart from the body and taught accordingly. No one can so well appreciate the relation of one to the other as the physician.

THE TREATMENT OF BRONCHO-PNEUMONIA IN CHILDREN.

M. Simon divides the different types of broncho-pneumonia into (1) the *foudroyante*, which kills the patient in two or three days; (2) the acute, which lasts seven or eight days and is very fatal; (3) the subacute, which may last three or four weeks. Whatever its type, broncho-pneumonia is a most serious disease, and, according to Simon, hardly fifty per cent. recover. The affection is one of special interest also because of its frequency and the difficulty attending its differentiation in some cases from acute phthisis. The remedies that have been usually recommended in treatment are emetics, expectorants, and stimulants, together with external applications. English writers, like Dr. Day, pin their faith on ipecac-wine, senega, and carbonate of ammonia. American writers lay less stress upon expectorants, but recommend at first small doses of calomel with bicarbonate of soda. The ammonia preparations, strychnia, quinia, and alcohol are then given. Only rarely are emetics or venesection used. German authors, like Henoch, speak favorably of ipecac, wet cups, and even tartar emetic in the vigorous class (a class most likely to get well in any event). In the majority of cases dry cups, hydropathic applications to the chest, camphor, benzoic acid, infusion of ipecac-root, and stimulants are to be recommended.

M. J. Simon has recently been delivering a series of interesting lectures upon this subject of broncho pneumonia in children. In that portion devoted to therapeutics we are struck, first, with the great change which has come over the therapeutical teachings of the French school since the days preceding the writings of MM. Barthez and Rilliet (1862). Still, M. Simon evidently does not accept the purely expectant treatment at one time advocated by the former author. In vigorous children he gives first a single emetic, not using, however, kermes mineral or antimony; neither, he adds, should such depressing agents as opium, belladonna, or aconite be given. On the other hand, some form of alcoholic stimulant should be administered, and quinine in doses of from one to four grains twice daily. The bowels should be kept open by repeated injections, or the use of magnesia or senna. External applications of mustard or flying blisters, followed by poultices, are also recommended. The temperature of the room should be equable, neither hot nor cold, dry nor moist. As an anodyne and sedative, if one is needed, chloral is advised in doses of five or six grains.

THE ART OF QUACKERY A HUNDRED YEARS AGO.

One hundred years ago Dr. Samuel Johnson wrote, referring to London physicians:

"A physician in a great city seems to be the mere plaything of fortune; his degree of reputation is, for the most part, totally casual; they that employ him know not his excellence; they who reject him know not his deficiency. By an acute observer, who had looked on the transactions of the world for half a century, a very curious book might be written on the fortunes of physicians."

At about the same time the celebrated Dr. Mead gave the following choice bits of advice, in a letter to a young London physician, on the art of getting a practice. It perhaps shows why the reputation of the physician was "totally casual."

"The first thing I advise you to do is to make all the noise and bustle you can, to make the whole town ring of you, if possible, so that everyone may know that there is such a being, and here in town, too, such a physician."

"The old and the simple, the riotous and the whimsical and the fearful, are your best company, and those who will provide you with most business. Or if you would be esteemed very wise, sober, and grave, you should then learn to fawn and soothe man, woman, and child, since few else will thrive unless blessed with wit, in which case they may be allowed a little more liberty.

"To make yourself known, the making friends for some public lectureship is not amiss.

"If you can be introduced to a hospital your business is done for life, be your success what it will.

"If your wife mind business in her way it will certainly increase yours.

"It will not be amiss to set up an equipage, to purchase a mountain of books, and add anything by which you will acquire the reputation of being a learned and ingenious gentleman.

"Let your religious and political opinions swim with the tide.

"Dancing and dressing well are not such slight accomplishments as you may imagine—his fashionable gesture and agreeable way of feeling the pulse is half the business.

"Should you have an itching to write a book on physic, I would advise you to choose a subject by which you think you will get most money, as fevers, small-pox, etc. For in those diseases some must always live, some die; it is a hard matter to tell when right or when wrong.

"And next, then, I would advise you, whatever the subject you write upon (if uncommon, the better), rather to write so as neither to make downright sense or nonsense thereof, than otherwise, because thus none of the profession can well lay hold of you for any particular part, or, if they should, there is room for you to defend it, being as easily understood one way as t'other."

One can hardly believe that the foregoing was written by one of the most distinguished and learned physicians of the eighteenth century. If written seriously, which we must doubt, Dr. Mead quite deserves the name of the Machiavelli of medicine. If written in satire, it is a gloomy picture of the methods well known to have been frequently employed in the last century, and abundantly explains Johnson's observations upon the fortune of physicians.

Medical reputation now is not gained by such methods nor lost by mere accident.

In noble contrast to the eighteenth-century sentiments is the counsel to young physicians recently given by Dr. Robert Battey: "If you want to succeed in life—in professional life, I mean—don't be too careful, when a call comes to you, to inquire into the circumstances of your patient, whether he is able to pay or not. Don't be too careful to prune closely at the outset and trim your practice into influential patients only, and all that sort of thing. Try to infuse within your own heart and soul a true spirit of benevolence, love of your kind, zeal for your profession, anxiety to relieve human suffering, and, if you pursue your mission with your whole heart, with true earnestness of purpose, *somebody* will find it out, and it will not be a great while before a great many people will find it out, and they are not going to let you starve. That sort of men is too scarce to let starve. They don't starve in America. They can't be spared. If you want to be sure of your bread and meat, and provender for your horse, and something for the blacksmith and carriageman, take that recipe and try it a while."

TWO EXPLODED PHYSIOLOGICAL DOCTRINES.

Theories regarding the finer details of the cardiac mechanism have been numerous and ingenious. One of the most attractive of these was the so-called "doctrine" of the *selbst-steuerung* of the heart, suggested first by Thebesius and later by Brücke. According to this, the aortic semilunar valves are pressed down over the orifices of the coronary arteries during the heart's systole, and no blood enters them at this time. In diastole, however, the mouths of these arteries are open and the recoiling blood is driven into them. Unfortunately for this view, the orifices of the coronary arteries are often situated too far above the semilunar valves to allow of such a succession of events; and for this and other reasons the doctrine in question has been generally abandoned.

Another theory, which has been still more widely accepted and taught, is that of the suction-action of the heart. Chapters on the physiology of the circulation very often begin with the statement that the heart is a suction- and force-pump. During diastole, we were told, the tense net-work of vessels supplying the cardiac muscle caused the walls to expand and the ventricular and auricular cavities to dilate. A negative pressure was thus produced, and the blood sucked in from the veins. Goltz and Gaule have shown that there is a negative pressure in the ventricles for a brief period at the end of each systole; but Moens, on the other hand, demonstrated that this did not affect the auricles, and therefore did not make the heart a suction-pump, so far as the veins and general circulation are concerned. Professor H. Newall Martin and Dr. Frank Donaldson, Jr., have recently performed a series of experiments on dogs, by which the matter in question seems to be definitely settled. Their experiments were conducted upon the heart exposed in the manner devised by Professor Martin, the thorax being open, the pulmonary circulation intact, and the systemic circulation substituted by a continuous supply to the heart of defibrinated blood. Then, by connecting a manometer with the right auricle, it was easy to determine whether any blood was sucked from the veins by the right heart. The outcome of the work is stated as follows: "The heart is not a suction-pump. Once the 'aspiration of the thorax' has been eliminated, the right auricle of the mammalian heart will not receive blood unless supplied to it under a decided, if small, positive pressure. While the heart in the closed thoracic cavity may, and probably does, act as a suction-pump, this is not due directly to an active expanding force of the heart, but is a secondary result of the pneumatic conditions prevailing within the normal closed chest-cavity. Any cause diminishing thoracic aspiration must therefore greatly hinder the work of the heart; and it is probably more in this manner that the circulation is impeded in certain cases of hydro- or pneumo-thorax than by direct pressure exerted on the heart itself."

The United States Veterinary Medical Association held its annual meeting in this city during the past week, and discussed several topics of interest. Among these was that of the epidemic of cerebro-spinal meningitis, so called, now prevalent in New Jersey. Dr. Huidekoper said that the ravages of the disease had been much exaggerated. Although called cerebro-spinal meningitis, it was not that at all. It was not contagious, but miasmatic. The Committee on Contagious Diseases reported that pleuro-pneumonia was at present confined to the vicinity of New York and the States of New Jersey, Pennsylvania, Delaware, Maryland, and Virginia. There are about two thousand cases in the vicinity of this city. The Committee on Securing Uniform Examinations for Veterinary Colleges throughout the country reported that the colleges were favorable to the plan, but no meeting to carry it out had been held. It is proposed to have all candidates for diplomas finally examined by a board not connected with any of the colleges. These officers were elected: President, R. S. Huidekoper; Vice-President, J. C. Myers; Secretary, C. B. Michener.

Another Alleged Medical College in Vermont.—The *Rutland Herald* states that "the Vermont Medical College, which opened September 1st, on West Street, has been incorporated under the laws of the State for the laudable purpose of educating teachers of the healing art." The dean is said to be a specialist in metaphysical science.

News of the Week.

The late Professor Alonzo Clark, M.D., LL.D.—At a special meeting of the Medical Board of Bellevue Hospital, held September 19, 1887, the following minute was adopted:

The Medical Board of Bellevue Hospital desires to express its deep sense of the loss it has sustained, in common with the medical profession of this country, by the death of its honored associate, Dr. Alonzo Clark. For a third of a century he has been closely identified with the interests of this institution, as a skilful and kind physician to its patients, a wise instructor of its successive house staffs and clinical classes, a consulting physician of large experience, profound learning, and sound judgment, and for many years as president of its Medical Board.

Dr. Clark possessed in a marked degree the qualities that belong to a physician of the highest type. He was a man of unusually impressive and dignified presence, with a manner of mingled firmness and gentleness, that commanded the respect and won the confidence of all with whom he came in contact. He was an acute observer, an accurate diagnostician, and though he was conservative in therapeutics, his conservatism was equally removed from obstinate adherence to old methods and rash experimentation with new ones. A lifetime student, he kept at the level of the best thought of his profession, but at the same time he was an acknowledged leader, and by his teachings and writings did much to elevate the standard of medical science in this country.

But to those who knew the personal character of the man, its simplicity, solidity, and symmetrical development, how incomplete a conception of him is given by a mere enumeration of his intellectual qualities, great as these unquestionably were. Nature not only built him on a large scale, but she left out of his composition most of the foibles which so often lessen our respect for, and impair the usefulness of, those whom the world regards as great men. No trait was more notable in him than his remarkable self-control. Nothing appeared to disturb his equilibrium; not because he was impassive, but because the foundation of his mental structure was laid too deep to be easily shaken. He was eminently a kindly man, charitable in his judgments of others, liberal in his benefactions, but so unostentatiously that none but his most intimate friends, and probably not even they, knew their frequency and extent; and, as some of us can testify, he was a true friend in time of sorrow.

His mortal life ended with a long and distressing illness, but he bore it with a brave and uncomplaining spirit. To the profession he loved and honored, he has left the fruit of his labors and the memory of a great and noble character.

A. B. Ball, M.D.,
Austin Flint, M.D.,
William H. Thomson, M.D.,
Charles L. Dana, M.D.

Hydrophobia Epidemic.—The excessively hot weather in Southern Russia is said to have produced an actual epidemic of rabies; and the Pasteurian Hospital at Odessa is overcrowded.

The Medical Record's report of the International Medical Congress will be found to be the most complete that has appeared.

The American Profession would feel more at ease regarding the success of the Congress, if its friends would not make such painful efforts to show that it was a brilliant and conspicuous success.

We find, with regret, that we must depose the Congress from the eminence of numerical superiority upon which we at first placed it. The actual number of registered delegates was considerably below three thousand, and of foreign delegates not much over one hundred.

Dr. Morell Mackenzie is to receive the honor of knighthood, in recognition of his services in the treatment of the Crown Prince of Germany.

The New York State Medical Association holds its fourth annual meeting at the Hotel Brunswick, in this city, on September 27th, 28th, and 29th.

Cholera Infantum.—A negative got omitted, and Dr. Maxwell was made to say, in our report of the International Medical Congress, that "heat was an essential factor in its causation." It should have been, "*was not*," etc.

The Willard Parker Hospital.—By resolution of the Health Board of this city, Dr. George F. Shrady has been added to the staff of consulting surgeons.

New York Polyclinic.—The sixth annual session of the New York Polyclinic opened on September 19th. The new laboratory for the study of bacteriology will be opened on October 1st. Two large lecture-rooms have been added to the college building since the close of the session of 1886–87.

The Post-Graduate Medical School opened its session on the 15th. A number of improvements have been made in the building, a new lecture room and reading room added, and an extension of the ground-floor will soon be completed.

Another Decoration.—It is rumored that the Emperor of Austria intends to confer a decoration of a high class upon M. Pasteur.

The Drug Clerks of Paris threaten to strike, on the ground of overwork and poor pay. Their ordinary round of work is given as follows: He rises at seven o'clock, and serves the ordinary morning customers who come for castor-oil, sulphate of magnesia, and *tisanes*. At ten he goes to the laboratory, and makes up syrups, after which he returns to the shop, when he takes his lunch. After this, up to eleven o'clock at night, he is engaged in making up physicians' prescriptions. Even when in bed he is doomed to hear the frequent ring of a bell which summons him to the shop or laboratory in the small hours of the morning.

Pilocarpin has been artificially made by synthesis. The process was discovered by two French chemists, MM. Hardy and Calmest.

A Spanish Congress of Gynecologists is to be held at Madrid next year.

An Ophthalmological Congress was held at Turin, September 15th to 18th.

The Governor of California has been suffering from a severe illness, which may by this time have proved fatal. He has been attended by a lady physician of the name of Buckel, who has made the somewhat remarkable diagnosis of abscess of one kidney. At the last accounts there was fear that the abscess would burst, "in which event there would be danger of blood-poisoning." Temperature 99°, and pulse 64. We should like to hear more of this remarkable abscess.

Death of Ex-Governor Luke P. Blackburn.—Dr. Luke P. Blackburn died at his home, in Frankfort, Ky., on September 15th, in the seventy-first year of his age. He was born in Woodford County, Ky. When seventeen he studied medicine in Paris, and graduated at a medical college in Lexington, Ky., in 1835. He began practice at Lexington. His career was a notable and unique one. He won his fame not by scientific investigations or by special skill in his practice, but in fighting epidemics. The appearance of cholera or yellow fever was to him like the smell of gunpowder to an old warrior. In 1836 at Versailles, in 1847, and in 1853 to 1855 at Natchez, in 1856 at Staten Island, in 1866 at Bermuda, and in 1878 in Kentucky, Dr. Blackburn distinguished himself in personally attending and in organizing relief for sufferers from cholera or yellow fever. He lived for a time at Natchez and New Orleans, but in 1860 took up his residence at Louisville, Ky. In 1879 he was elected governor of the State. Since then he had continued in the practice of his profession until shortly before his death.

A Judicial Decision regarding Death from Anthrax.—In a recent case (says the Philadelphia *Medical Times*) the United States Mutual Accident Association refused to pay a policy where the assured died with malignant pustule. It appeared that the deceased was employed at a place where hides and cattle were received, and that the cause of death was "a putrid animal substance on the exterior of the body working inwardly, and usually communicated from the bodies of animals suffering with diseases of the hair." The policy insured against death from "external, violent, and accidental means," and excepted death "by taking poison." The question was whether there could be a recovery under the policy, and the court decided that there could be. The course of reasoning by which the learned judge reached this conclusion was somewhat curious. By the same rule death from erysipelas or syphilis might be considered accidental, for these are produced by external causes, in some cases, at least, accidental.

Increase of Blindness in the United States.—Dr. Lucien Howe read a paper on this subject at the last meeting of the American Association for the Advancement of Science, in which he said that while the population, during the ten years from 1870 to 1880, increased at the rate of thirty per cent., blindness during the same time increased one hundred and forty per cent. The statistics also show that blindness increased in an almost constant ratio from north to south in the United States, and that it decreased in the same way from east to west. The cost of sustaining this army of more than fifty thousand blind, if estimated on the lowest basis of cost and wages which should have been earned, amounted to more than $16.-000,000 in 1880, or more than $25,000,000 in 1887. Contagion and immigration were among the chief causes of this increase.

M. Richet has been appointed Professor of Physiology in the Faculty of Medicine of Paris.

Carbolic Acid in Otitis.—Dr. Hartamann during the last year has treated moderate otitis with instillations of several drops of a solution (1 in 10) of carbolized glycerine. The results were excellent. Pain instantly disappeared, and the progress of the affection was checked. In cases where effusion existed the relief obtained was equally great. M. Rohrer, who confirms M. Hartamann's statements, recommends a solution of twenty per cent.—*Brit. Med. Journ.*

The Secret of Petrifying Animal Bodies.—The secret of the method of petrifying human and other bodies, which was discovered by Dr. Massedaglia in the early part of this century, has never been revealed, and the curiosity of those who are anxious to know it seems unlikely to be gratified at present, at least. When the discoverer died he left a description of the method in a sealed packet to his "lawful heirs," but no lawful heirs have come forward until just recently, though Dr. Massedaglia died more than forty years ago. It is said that immense sums have been offered for the secret, but that the fortunate possessors are in no hurry to share it with anyone else. Some bodies of animals petrified by Dr. Massedaglia himself are, we believe, to be seen in the museum of the University of Padua.—*Brit. Med. Journ.*

Reporting Contagious Diseases.—The Health Board is disposed to do everything in its power to aid physicians in reporting contagious diseases, and we are quite sure that the result will be successful. Addressed postal cards are to be sent to physicians desiring them.

Etiology of Dysentery.—Professor Jaroslav Hlava, of Prague, has examined (*Pizeglad Leharski*, February 12, 1887) the stools and the intestines, with their contents, in sixty fatal cases of epidemic dysentery, two of sporadic, and ten in which the disease occurred as a complication of other affections. Recent stools from dysenteric patients were injected into the rectum or duodenum in seventeen dogs, six cats, eight rabbits, and in hens and guinea-pigs. In addition to this, seventy injections of pure cultivations of various bacteria which had been found in stools and intestinal contents were made. From those extensive observations Professor Hlava was led to the following conclusions: 1. Bacteria are not the cause of dysentery, since the disease cannot be produced in animals by introducing into them any microbes found in persons suffering from the affection. A simple passing intestinal catarrh is all that can be induced in that manner. 2. The injection of stools gives rise to dysentery only in cats. 3. There is no specific anatomical difference between epidemic and sporadic dysentery. 4. There are present in the stools (and sometimes in the mucous and submucous coats of the bowel) long or oval amœbæ with a granular protoplasm, which move about under the objective glass for ten hours. In sixty-five cases the amœbæ were very numerous. Dr. Hlava is now studying the question of their relation to the disease.—*British Medical Journal.*

Reports of Societies.

THE AMERICAN GYNECOLOGICAL SOCIETY.

Twelfth Annual Meeting, held in New York, September 13, 14, and 15, 1887.

TUESDAY, SEPTEMBER 13TH—FIRST DAY—MORNING SESSION.

THE Society convened in the Hall of the New York Academy of Medicine, 12 West Thirty-first Street, and was called to order by DR. ALEX. J. C. SKENE, of Brooklyn, President. Dr. John C. Reeve, of Dayton, O., First Vice-President, occupied the chair to the President's left, and Dr. George Granville Bantock, President of the London Obstetrical Society, was invited to occupy the chair to the President's right.

THE CALLING OF THE ROLL.

The Secretary, DR. JOSEPH TABER JOHNSON, of Washington, D. C., then called the roll, and the following Fellows responded: Fordyce Barker, of New York; W. H. Baker, of Boston; B. B. Browne, of Baltimore; S. C. Busey, of Washington; John Byrne, of Brooklyn; James R. Chadwick, of Boston; E. L. Duer, of Philadelphia; Thomas Addis Emmet, of New York; Frank P. Foster, of New York; Henry J. Garrigues, of New York; William Goodell, of Philadelphia; Charles M. Green, of Boston; William T. Howard, of Baltimore; James V. Ingham, of Philadelphia; A. Reeves Jackson, of Chicago; Jos. E. Janvrin, of New York; E. W. Jenks, of Detroit; Charles Jewett, of Brooklyn; A. F. A. King, of Washington; Charles Carroll Lee, of New York; William T. Lusk, of New York; H. Marion Sims, of New York; R. B. Maury, of Memphis, Tenn.; Paul F. Mundé, of New York; C. D. Palmer, of Cincinnati; Theophilus Parvin, of Philadelphia; John P. Reynolds, of Boston; William L. Richardson, of Boston; Ely Van de Warker, of Syracuse, N. Y.; H. P. C. Wilson, of Baltimore. The following, in addition, were present during the course of the meeting: G. J. Engelmann, of St. Louis; W. R. Gillette, of New York, James B. Hunter, of New York; A. W. Johnstone, of Danville, Ky.; M. D. Mann, of Buffalo, N. Y.; Ellwood Wilson, of Philadelphia; W. Gill Wylie, of New York.

The following gentlemen were elected

INVITED GUESTS:

Drs. Graily Hewitt and G. G. Bantock, of London, England; Augustus Martin, of Berlin, Germany; A. Cordes, of Geneva, Switzerland; A. R. Simpson, of Edinburgh; Georges Apostoli, of Paris, France; Dr. Frome, of Edinburgh; G. H. Kidd, of Dublin, Ireland; Lloyd Roberts, of Manchester, England; William L. Reid, of Liverpool, England; J. Milne Chadbourne, of Inverness, Scotland; J. Amédé-Doleris, of Paris, France; A. E. Aust-Lawrence, Nelson C. Dobson, and T. M. Dolan, of England; W. Balls-Headly, of Melbourne, Australia; Walter Brown, of Belfast, Ireland; J. A. S. Grant (Bey), of Cairo, Egypt; Professor Terrier, of Paris, France; G. Bernard, John Gould, John Sivins, Boyd Jole, of England; Valentine Knaggs, J. Comeys Leach, Foster McGeah, Thomas Logan, Fred. Morgan, Dr. Parkinson, R. Singleton Smith, and Dr. Wiseman, of England; J. H. Davenport, and G. W. Porter, of Providence, R. I.; Dr. Moseley, of Baltimore, Md.; William J. Aiken and James H. Stowell, of Chicago; W. W. Potter, of Buffalo, N. Y.; W. W. Seymour and Z. Rousseau, of Troy, N. Y.; Drs. Beebe, of Minnesota; Henry Hewitt, of Guelph, Ontario; M. Ogden, of Toronto; A. Van Derveer, of Albany, N. Y.; William Gardner, of Montreal; Lincoln McPhatter, of Guelph, Ontario; Dr. Banajee, of Bombay; J. Algeron Temple, Toronto, Canada; Augustus C. Burnays, of St. Louis, Mo.; William H. Haggard and W. D. Atchison, of Nashville, Tenn.; A. S. Hunter of New York; John Chambers, of Indianapolis; B. C. Hirst, of Philadelphia; Dr. Harvey, of Indianapolis; Ed. Mitchell, of Cincinnati; R. P. Harris and Howard N. Kelley, of Philadelphia; X. O. Minder, of Pittsburg; D. A. K. Stelle, of Chicago; Richard J. Thompson, of Fall River, Mass.; F. A. Flandreau, of Rome, N. Y.; E. W. Cushing, of Boston; N. S. Davis, of Chicago; Dr. Lonaker, Dr. Barnes, and W. C. Cook, of Nashville; J. H. Raymond, of Brooklyn; Robert L. Dickinson and Benton Butler; A. B. Palmer, of Ann Arbor; E. Landolt, of Paris, France; Duncan C. McCallum, of Montreal; all the members of the New York Obstetrical Society.

FORDYCE BARKER, M.D., LL.D., of New York, then delivered

THE ADDRESS OF WELCOME,

and in behalf of the resident Fellows of New York and Brooklyn, and of the Fellows of the New York Academy of Medicine, and of affiliated societies having the same aims and objects, welcomed the Fellows of the American Gynecological Society and the friends who had honored them with their presence.

Referring to the work which the Society had already done, Dr. Barker said:

"In the aggregate it may be asserted that both talent and genius have been developed and consecrated to these departments.

"I remember to have somewhere met this terse distinction between Talent and Genius: 'To do easily what others do with difficulty, that is Talent. To do what Talent cannot do, that is Genius.'

"Owen Meredith, now Lord Lytton, gave expression, some twenty-five years ago, to the same thought in the following couplet:

> "'Talk not of Genius baffled. Genius is master of the man.
> Genius does what it must, and Talent what it can.'

"To our foreign guests I will say, many of you are well known to many of us personally. All of you are well known to all of us by the good work that you have done. We give you a warm welcome, with the anticipation that the interest of this meeting will be largely enhanced by your participation in its work.

"We hope that you will find our hospitalities acceptable and agreeable, and we feel assured that you will leave behind you a warm place in our hearts, which will bind us in as close affinity in our personal affections, as we now are united in sympathy in our professional work.

"We welcome also our friends of this city and from other parts of the country, whose interest in the subjects to which we are devoted brings them here to watch our proceedings and to stimulate us to our best efforts.

"It only remains, Mr. President, for me to congratulate you that you have the honor to preside over such a body, and to congratulate the Society that it has you as its presiding officer. I will only say for ourselves, *Cuncti adsint, meritæque expectent premia palmæ.*"

The first paper was read by DR. THOMAS ADDIS EMMET, of New York, entitled,

A STUDY OF THE CAUSES AND TREATMENT OF UTERINE DISPLACEMENT.

Close observation and a long experience, said the author of the paper, have been of but little avail, if it be true that the version of the uterus is the disease, and if a simple change in the extent of the deviation be the remedy for the displacement.

Moreover, his experience had taught him that the degree of prolapse below, or the elevation of the uterus above, *a certain plane*, caused the symptoms now usually attributed to version alone. Years ago he had pointed out what he had termed "the health line," one that varies in each woman, but so long as the uterus occupies it, circulation remains normal.

Anteversion of the uterus certainly is not an abnormal position. Retroversion, to a very marked degree, is frequently detected accidentally, not the least inconvenience ever having been produced by it.

The causes of displacements to which he directed special attention were the *external, and due to pelvic inflammations.*

There is a large class of cases which belong under this head, but which have not received the attention that their importance demands.

With a backward or a forward displacement, the only relief to be obtained must be through some means which will correct the prolapse sufficiently to restore the circulation.

When the uterus has been displaced in either direction, as the result of peritoneal inflammation situated on the anterior face of the broad ligaments, any attempt to correct the version will not succeed unless the same principle be kept in view. When the inflammation has been limited to one side, most frequently upon the left, it is equally impossible to devise any pessary which will not make direct pressure, and in time increase the difficulty by exciting a fresh attack of local peritonitis.

The question may be asked, "What is the general practitioner to do with such cases?" His answer would be—if he is an honest man and considers the future well-being of his patient—let such cases alone, so far as making any attempt to correct the displacement. If it be absolutely necessary to undertake some mode of treatment, it should be confined to local application of iodine, with cotton and glycerine pads properly placed *to give needed support,* and to the use of hot-water vaginal injections. The treatment of such cases should never be attempted outside of a hospital service, and never would be were the consequences sufficiently understood.

Dr. Emmet then pointed out some of the peculiar features of the pelvic circulation of the female, its close relation to the surrounding fascia and connective tissue.

The whole skill in the successful application of a pessary is to so contruct it that, while it relieves the prolapse, it will just dispose of the over-stretch. A pessary does not give relief by simply counteracting version. Its effect is an indirect one, because, when properly fitted, it diminishes congestion by correcting the prolapse and giving tone to the connective tissue of the pelvis. If a uterus, free from peritoneal adhesion, be replaced and a sufficient support to the fascia be again brought into play, it will then be retained in position through the natural elasticity of the surrounding tissues.

Lest that he might hereafter be misrepresented by the statement that he did not approve of the use of pessaries, Dr. Emmet wished to say that, while the profitable range for the use of these instruments was not an extensive one, he believed that nothing could take the place of a pessary when properly fitted, and when used in the proper class of cases. The field of usefulness for the instrument, however, was much more limited than was generally supposed. It was not to be expected that a man who prides himself on his skill in fitting a pessary would change his practice, yet he might mistake as an evidence of his dexterity the degree of tolerance with which the Almighty in his infinite wisdom had endowed the female pelvis. A displacement should never be corrected simply on its own account, nor until the cause has been clearly ascertained. No attempt should be made to correct a displacement of the uterus so long as any evidence of recent inflammation in the neighborhood can be detected. If the displacement be a recent accident, the practice, as in case of luxation, would be correct to reduce it at once.

Dr. Graily Hewitt, of London, said that he had not met with a large number of cases in which pelvic cellulitis had been associated with uterine displacements, and from what knowledge he had been able to obtain on the subject, it appeared that there was possibly a difference in the constitution of the women of America and England, which rendered the former more than the latter liable to the occurrence of this form of inflammation. It might be an error on his part that he had not detected it in his cases, but he had attributed the sufferings of his patients to something else. He must say that he regarded the general causes of displacement of the uterus as one of the most important subjects which could be brought before the profession. With all these causes Dr. Emmet had already showed himself by his writings to be familiar, and none was more important than the general nutrition of the patient. Dr. Hewitt then alluded to pressure upon the nerves of the uterus itself as an important factor in estimating the cause of the suffering of the woman, perhaps as important as the disorders of the circulation mentioned by Dr. Emmet.

Dr. A. R. Simpson, of Edinburgh, thought it was easy to see that there were two distinct camps, represented by the two eminent speakers by whom he had been preceded. He thought that there was not so much difference in the constitutional peculiarities of American and English women as there was between practitioners who had been specially impressed with the importance of different causes of uterine displacements. He then spoke of a class of cases in which there was displacement with sterility, without history or evidence of pelvic inflammation, and when the uterus had been restored to its normal position the women had, in many instances, soon afterward conceived and borne children. He made this reference because there seemed to be a slight tendency in some quarters to abandon the use of the pessary, and he thought that it should not be abolished altogether.

Dr. George G. Bantock, of London, was sorry that he was unable to agree with Dr. Emmet concerning the frequency of pelvic inflammation, and he thought that perhaps the diversity of opinion on this point had been best explained by Dr. Simpson—namely, very much depends on the condition of the mind of the man who makes the examination of the case. As the result of his own experience, he had come to believe that the occurrence of pelvic inflammation was much more rare than had been generally supposed. He thought it had been proved beyond contradiction that the so-called cases of pelvic cellulitis were cases of salpingitis—cases in which the inflammation has been confined to the Fallopian tubes and the tissues in their immediate neighborhood.

If, therefore, the question of the occurrence of pelvic cellulitis could be removed, he thought that the treatment adopted by Dr. Emmet and himself in similar cases would be about the same. The failure of the pessary to afford relief in many cases has been because it had been improperly adjusted. There were certain cases of well-marked retroversion in which nothing more was required than replacing the uterus at once, and always by means of the sound, and the proper application of a pessary, to give complete relief from all the symptoms, such as bearing-down sensation, vesical tenesmus, etc. But when adhesions exist which hold the uterus in malposition, the use of a pessary at first would be perfectly useless, if not injurious.

Dr. Emmet in closing the discussion directed special attention to the fact that the examiner would remain in profound ignorance of the condition of the contents of the pelvis unless he examined *by the rectum.* It was utterly impossible to detect fully the inflammatory trouble by vaginal examination, and that was one explanation of the diversity of opinion concerning its existence. That the occurrence of pelvic peritonitis and cellulitis was common among the women of this country he was fully convinced. This conclusion was the result of many years' experience, and he knew it was true.

Dr. Samuel C. Busey, of Washington, then read a paper on

CYSTOCOLPOCELE, COMPLICATING LABOR AND PREGNANCY.

The word cystocolpocele was introduced to express correctly the anatomico-pathological conditions of prolapse

of the bladder into the vaginal passage. It might be partial or complete. Some of its synonyms were "vaginal vesicocele," "vaginal hernia," "vesical hernia," etc.

There were only six cases on record of this affection *complicating pregnancy*. The author of the paper gave a brief outline of each of these, together with one occurring in his own practice.

CYSTOCOLPOCELE COMPLICATING LABOR,

though rare, was far more common than that complicating pregnancy. As a hindrance to, and a cause of, lingering and painful labor, it had received general, if not adequate, attention from a few of the more recent writers on obstetrics. Multiparity is an essential and a constant factor of causation, but it must have a coefficient, such as a change in the relation of the pelvic viscera resulting from childbearing, etc. Lingering labor is the constant and most prominent subjective symptom, characterized by acute, ineffective pains. The objective symptoms can be discovered only by intelligent vaginal examination. The only positive, absolutely certain symptom is the discharge of urine from the urethra, and the lessening or entire subsidence of the swelling.

The treatment consists in the speedy and complete evacuation of the bladder, which usually permits rapid progress of labor. This can be accomplished by the catheter, or by the skilful manipulation of the cystocele, or by the two combined.

Dr. W. Goodell, of Philadelphia, reported a case which he encountered in his practice, and which at first gave him a great deal of annoyance.

Afternoon Session.

The Society was called to order by The President.

Dr. W. M. Polk, of New York, read a paper with the title,

ARE THE TUBES AND OVARIES TO BE SACRIFICED IN ALL CASES OF SALPINGITIS?

By the term salpingitis the author of the paper meant the disease which until recently was known by the name of pelvic cellulitis, and characterized by inflammation of the planes of cellular tissue belonging to the uterus and its appendages. According to its behavior, it has been called acute, chronic, and recurrent cellulitis and peritonitis. The most constant change produced by the adhesions was dislocation and imprisonment of the tubes in faulty positions, the outer openings were frequently closed, and no doubt the parenchymatous changes in the walls of the tubes were in part the result of the adhesions. The ovaries were likewise involved in the new connective tissue, and often, by being bound down, were deprived of that freedom of movement and ability to expand which were essential to the proper performance of their functions. The mobility and distensibility of the uterus were also greatly impaired.

The clinical evidences of the disease represent the general and local signs of an inflammation, the local evidence being greatly colored by the peculiar organs involved. The symptomatology of salpingitis has become familiar, as it has been described under the heading "pelvic cellulitis and peritonitis."

The observations which had led the writer of the paper to that conclusion were made in one hundred cases, and the argument on the question appeared in The Medical Record for September 18, 1886. Dr. Polk had framed his question that it might be pushed into the domain of that large class of sufferers who, remaining invalids, have no chance of efficient relief except in laparotomy. Had he been asked, one year ago, whether the tubes and ovaries should be sacrificed in all such cases of salpingitis, he would have replied "Yes." But some experience since had caused him to doubt the accuracy of that conclusion. In comparing the pathological conditions with the histories in his cases, it occurred to him that the *adhesions* might be the potent factor in sufferings endured. If so, it was evident that a cure might be effected by simply freeing the imprisoned organs.

Granting the result of health and comfort claimed for this disruption, the next question was the utility of leaving the occluded tube in position. For the purpose of procreation, there was, perhaps, no utility; but for the purpose of satisfying the patient's desire to escape mutilation, yes. The excuse for mutilation is to save life and to restore and insure health. Do this without mutilation and the requirements are answered, and the object of the paper was to show that it can be done in certain cases. Brief mention was made of eight cases.

Dr. A. Martin, of Berlin, Germany, was pleased to hear that Dr. Polk did not propose to call every tumor of the tube a salpinx, as he believed progress could be made only by distinguishing the different diseases of this organ. It had been supposed that salpingitis is of gonorrhœal origin very often, but in only a few cases has the gonococcus been found in the tube. One of these cases he found some months ago, and it was the second which had been recognized. Dr. Martin never contemplated removal of the uterine appendages without a great deal of anxiety. He had reached the conclusion that in certain cases the operation is demanded. Well-marked cases of pyo-salpinx, whether of gonorrhœal origin or not, will sooner or later require operative interference. And yet he was sometimes in doubt as to the correctness of that opinion when he found only a small quantity of cheesy matter, because it was evident that such cases were capable of curing themselves. He did not believe that cases of simple catarrhal salpingitis were proper ones for operative procedure. More serious still were the cases of hæmato-salpinx.

The discussion was continued by Dr. T. Addis Emmet, of New York; William Goodell, of Philadelphia; and G. G. Bantock, of London, who would unhesitatingly answer in the negative Dr. Polk's question.

Dr. Martin was inclined to regard Dr. Polk's proposed method of treatment very much as had Dr. Goodell—that is, if the tube be diseased and also the ovaries, they should both be removed; for in that way the salpingitis was removed and any displacement present corrected.

Dr. Sutton, of Pittsburg, could not agree with all the speakers in answering the question in the negative.

Dr. W. Gill Wylie, of New York, with a death-rate under five per cent., would now operate in cases in which a few years ago he would not have attempted the operation.

Dr. Emmet believed it to be a reflection on the profession to remove ovaries and tubes to cure symptoms due to anæmia, or to remove these organs without disease except the mere presence of a few cysts.

The discussion was closed by Dr. Polk.

Dr. Paul F. Mundé, of New York, then read a paper on

DRAINAGE AFTER LAPAROTOMY.

The questions which appeared to require answer in the study of this subject were: (1) In what class of cases does drainage theoretically seem necessay? (2) What are the advantages of drainage? (3) What are the disadvantages and the dangers of drainage? (4) What form of drainage is the best, and least dangerous? (5) What substitute can be offered for drainage, or how can the necessity for its employment be avoided?

Dr. Mundé's conclusion was that in those cases where hitherto drainage has been largely employed, the drainage-tube could be dispensed with if there was only slight bloody oozing and serous secretion, provided the peritoneal cavity be thoroughly cleansed and the most universal and scrupulous antiseptic precautions be observed during the entire operation.

Dr. Martin, of Berlin, does not use the drainage-tube in ordinary cases of ovariotomy. He employs it in supra-vaginal hysterectomy, in vaginal hysterectomy, and in all those cases where he must have a large sloughing surface or cavities in the broad ligament.

Dr. Bantock, of London, has such confidence in the value of the drainage-tube that he employs it on the slightest excuse.

Dr. William Gardner, of Montreal, should continue to use the drainage-tube until further experience changed his confidence in the procedure.

Dr. Goodell, of Philadelphia, is a believer in the drainage-tube, and Dr. Wylie, of New York, believes that it has a special advantage in affording a means of determining whether or not hemorrhage is taking place.

Dr. Mundé closed the discussion, and the Society adjourned to meet at 9.30 A.M. on Wednesday.

Wednesday, September 14th—Second Day—Morning Session.

The Society was called to order by The President, who in a few well-selected words referred to the death of Dr. John Scott, of San Francisco, Cal., and appointed Dr. Thomas Addis Emmet, of New York, to prepare a memoir for the volume of "Transactions."

Dr. C. D. Palmer, of Cincinnati, then read a paper on

THE THERAPEUTIC VALUE OF SOME MEDICINES IN THE TREATMENT OF HEMORRHAGIC CONDITIONS OF THE UTERUS.

The writer referred to the fact that only five papers had been read before the Society on the therapeutic uses of medicines in gynecology, while at the same time there had been no lack of surgical contributions. He thought that too little attention had been paid to the less brilliant medicinal treatment. Uterine hemorrhage could often be treated advantageously by means of drugs, and those to which he directed special attention were ergot, digitalis, bromide of potassium, arsenic, gallic acid, cannabis indica, hamamelis, gossypium, viburnum, hydrastis, and the use of cholagogue cathartics.

The paper was discussed by Dr. Fordyce Barker, of New York, who spoke of the great advantage to be derived in certain cases from medicinal treatment.

Dr. D. Lloyd Roberts, of Manchester, England, thought that if a single choice must be made of drugs to be used for the purpose of controlling uterine hemorrhage, ergot would be selected. The next best remedy, according to his experience, was gallic acid.

Dr. Balls-Headley, of Melbourne, Australia, could not understand how these remedies could act in many cases, without being supplemented by local measures. He spoke of the advantages of the tincture of the chloride of iron.

The discussion was continued by Drs. J. A. S. Grant (Bey), of Cairo, Egypt; H. P. C. Wilson, of Baltimore; J. R. Chadwick, of Boston; W. L. Reid, of Liverpool, England; and the discussion was closed by Dr. Palmer.

Dr. J. Amédé Doleris, of Paris, France, then read a paper, in French, on

ALEXANDER'S OPERATION,

as a remedy for uterine displacements. In the first part of the paper the writer spoke of the normal conditions of the pelvic contents, and in the second part of the displacements suitable for the operation.

The paper was discussed by Drs. A. Cordes, of Geneva, Switzerland; W. L. Reid, of Liverpool; A. Martin, of Berlin; W. T. Lusk, H. Marion Sims, C. C. Lee, of New York; Aust-Lawrence, of Bristol, England; and Howard N. Kelley, of Philadelphia.

The First Vice-President, Dr. J. C. Reeve, of Dayton, O., was called to the chair.

THE PRESIDENT'S ADDRESS.

Dr. Alex. J. C. Skene, of Brooklyn, N. Y., President, then delivered his address, in which he said that at this stage of the Society's existence and progress a few moments might be profitably occupied in reviewing its structure and functions, the objects which it has already attained, and in looking forward to its future possibilities. These were given in the form of a light interlude, "to fill the half-hour between the two grand acts of the drama, to occupy but not to tax your minds."

The good work which had already been done suggests that this Society was one of the products of necessity, that worthy progenitor whose children inherit the genius of invention, construction, and all consequent usefulness

It was the design of the founders of this Society that it should be devoted to the advancement of science and art, and the cultivation of the higher social elements of life; not an organization to regulate the relations between doctors of medicine and the people, nor to maintain the rights and privileges of the medical profession as a trade, but something far higher in which human action is guided by inherent honesty and nobility of character, which needs no written law to prompt gentlemanly behavior, a Society in which men act well their parts because they desire so to do, and not because of any obligation, either ethical or otherwise. Without royal patronage or help, without the hinderance of political intrigue, but with a constant devotion to the cultivation of gynecology and the friendly relation of its Fellows, this Society, though young, stands to-day among the imperial organizations of the world, a strong and prosperous republic, in which all men are monarchs, crowned with honor, honesty, and intelligence, and wearing the royal robes of justice, benevolence, and beneficence, and decorated with their own good deeds toward their fellow-men.

The social element in the complex constitution of the human mind had, no doubt, much to do with the genesis of this organization, and it certainly has been a guiding power in all that has been accomplished so far.

The usefulness and promise of medical societies depend largely upon their objects. They are short-lived when created for personal interest, but enduring as time itself when called into existence by the necessities of men, and for the benefit of the whole human race.

From the time this Society was organized until to-day, the major portion of its time has been devoted to surgery; this is neither necessary nor best. A higher cultivation would enable men to listen with as profound an interest to the details of the management of functional and organic diseases by the physician, as to the record of some marvellous case in which the surgeon removes all except the organs absolutely necessary to the existence of the patient.

A careful weeding out of many of the old and useless operations, a more judicious selection of cases for operative treatment, more positive knowledge and generally accepted views upon pathology, and more confidence and skill in the use of medicinal agents would bring greater relief to the suffering, and give more of variety of thought and action to the gynecologist, who, in this age, is too often seen plying his needle and thread until his fingers are weary and worn, and his eyelids heavy and red.

Above and beyond there are still unknown fields to be explored, fields that will contribute largely to the wants of humanity. The greatest of all is that of preventive medicine. The gynecologist has much to accomplish still in this department.

The man who by his wise counsel can guide the development of the chlorotic child so that she may attain health and strength at her majority, has surely a higher claim upon the gratitude of all than the one who labors to counteract the many frailties of those who suffer through life with chlorosis. A large percentage of the time of the practitioner is spent in trying to relieve those

who, from defective development of the sexual organs, suffer from a long list of diseases. All kinds of operations have been devised, and a vast number of mechanical contrivances have been invented, to cure anteflexion of the uterus, for example, and most of them have proved of little value. But hardly anything has been said or done to guard against these evils, most of which are no doubt preventable.

The greatest honor (ephemeral, it is true) is at the present time bestowed upon the one who does the most to combat the results of disease and injury; but the time must come when the man who does the most to prevent these will be recognized as the greatest hero. There is, no doubt, good reason why this should be so in our present state of near-sightedness. The cure of disease and the relief of suffering appeal to our senses, and can be appreciated by the most superficial observer, but the prevention of disease can only be comprehended through our higher reasoning faculties.

In this country there is too much writing in proportion to the thinking and acting. Many of the most copious writers are not the most distinguished in practice, nor the most judicious readers. The pens of such men remind us of the sword of Don Quixote, but nevertheless they obtain a following of Sancho Panzas.

If the published cases could be submitted to a supreme court, and a decision obtained from competent judges after a full discussion, medical literature would be greatly improved. But as it is now, the reviews of works of the masters in medicine are often written by their pupils, and are usually a hallelujah chorus with a grand amen.

Should fate determine that gynecology shall have its rise, decline, and fall, like many of the nations and their works in the past, I predict that when the men of the future come to explore the ruins of the once mighty Gotham, while they may find in the débris modifications of Sims' speculum, quaint and curious uterine supporters, and many musty jars with human ovaries and tubes, they will also find the works of great masters and their monuments in perfect preservation, including the transactions of the American Gynecological Society, and especially the volume of 1887.

Dr. Elwood Wilson, of Philadelphia, Second Vice-President, in the chair.

Dr. George Granville Bantock, F.R.C.S., of London, England, read a paper on

THE TREATMENT OF THE PEDICLE IN SUPRA-VAGINAL HYSTERECTOMY.

In the first case in which he used Centrat's *serré-nœud* he found it inefficient, and was obliged to substitute Koebrele's, which he subsequently altered, and produced the instrument that he now employs. He prefers soft annealed iron wire to either copper or steel. He summarized his management of the pedicle in supra-vaginal hysterectomy as follows:

First.—The broad ligaments may be so long, and the ovaries so easily raised from the pelvis, that the whole can be included in the loop without difficulty.

Second.—One ovary may be included, while it may be necessary to ligate the other separately.

Third.—It may be necessary to ligate both ovaries separately.

Fourth.—The tumor may grow between the folds of either broad ligament, so that it must be partially included.

Fifth.—The tumor may be situated so low down in the body of the uterus that it may be necessary to separate it largely from its peritoneal covering before a sufficient pedicle can be formed.

The proper recognition and management of these complications severely test the judgment and coolness of the operator, and can only be learned by experience.

In regard to the after-treatment of the stump, the main object was to keep it dry; therefore, the dressings should be changed as soon as they become moist. There was no hurry about getting rid of the stump so long as it kept dry.

The discussion was postponed until Thursday morning.

Second Day—Afternoon Session.

Dr. James B. Hunter, of New York, read a paper in which he reported a case of

ACUTE DILATATION OF THE STOMACH FOLLOWING LAPAROTOMY.

The patient was twenty-five years of age, married four years, but never pregnant, and had been the subject of long-continued treatment. The operation consisted in removal of both tubes and ovaries for disease of the latter organs of several years' standing, and gave rise to severe dysmenorrhœa. The patient vomited at intervals after the operation until her death, which took place on the eighth day, the vomiting being peculiar in that large quantities of fluid were regurgitated without much straining. The abdomen became greatly distended, and it was supposed that there was a low form of peritonitis. The autopsy revealed extreme dilatation of the stomach. There was no evidence of either recent or old peritonitis. There was no obstruction at the pylorus. The history of the case and the results of physical examination showed that the dilatation took place after the operation.

Dr. A. Reeves Jackson, of Chicago, then read a paper on

THE INTRA-UTERINE STEM IN THE TREATMENT OF FLEXURES.

The object of the paper was to present the results that he had observed to follow certain plans of treatment when applied to selected cases, and to explain the details of the method employed.

The single symptom which he requires for the treatment of flexion is dysmenorrhœa. The essential principle in the treatment consists in its slow, gradual conduct. The uterus must be coaxed and not forced into proper shape. He never uses the stem in any case of flexion in which the deformity is not the cause of the dysmenorrhœa, nor until the tolerance of the uterus has been ascertained by previous systematic introduction of the bougie, nor when there is the least evidence of peri-uterine inflammation.

Dr. M. Ogden, of Toronto, was in accord with Dr. Jackson's paper.

Dr. Aust-Lawrence, of Bristol, England, said that his method of using the intra-uterine stem was very much the same as Dr. Jackson's.

Dr. Apostoli, of Paris, France, then read a paper in French on

THE TREATMENT OF UTERINE FIBROIDS BY ELECTROLYSIS.

The author of the paper began in 1882 to practise electrolysis in cases of uterine fibroid, directing the treatment mainly to the interior of the uterus, because:

1. The endometrium is nearly all diseased in cases of fibroma, hence the hemorrhage will be arrested by cauterizing it.

2. By modifying the nutrition of the mucosa, that of the adjacent neoplasm is also affected.

3. By introducing one pole into the uterus the operator is able to place the organ directly in the current.

The writer was accustomed, in all forms of metrorrhagia, invariably to place the positive pole within the uterine cavity, using the negative pole in other cases.

The paper was discussed by Dr. Chadwick, of Boston, and Dr. Apostoli answered some questions asked by Dr. Sutton, of Pittsburg.

Dr. James R. Chadwick, of Boston, read a paper on

THE OPERATION FOR VENTRAL HERNIA AFTER LAPAROTOMY.

The history of these cases shows that the hernia does not result immediately after the operation, but appears a year or more later. Strangulation has not occurred in any hernia after laparotomy. It has not yet been ascertained what method of closing the original wound will prevent the occurrence of the hernia. While perfect union of the peritoneum may tend to favor the union of the musculo-aponeurotic layers external to it, there was no reason to believe that the condition of the peritoneum has any effect upon the development of the hernia. Judgment, guided by experience and the correct appreciation of the individual differences of cases, must determine the proper distance between the sutures, and the tension of the abdominal walls after the operation must be kept at the minimum. Dr. Chadwick described the technique of the operation in a case of very large ventral hernia in which he succeeded in effecting a cure.

This paper was discussed briefly on Thursday afternoon by Dr. Lloyd Roberts, of Manchester, England; Dr. Harvey, of Indianapolis; and Dr. A. W. Johnstone, of Danville, Ky.

Thursday, September 15th—Third Day—Morning Session.

The Society was called to order by Dr. John C. Reeve, of Dayton, O., first Vice-President.

DISCUSSION ON DR. BANTOCK'S PAPER ON THE TREATMENT OF THE PEDICLE IN SUPRA-VAGINAL HYSTERECTOMY.

Dr. A. Martin, of Berlin, gave a brief outline of the history of the treatment of the pedicle in this operation, referred to the causes of death, as sepsis, etc., and finally said that dropping the pedicle was restoring as much as possible the normal condition of the intra-peritoneal organs.

Dr. A. R. Simpson, of Edinburgh, thought that it could not yet be settled for all cases whether the one or the other method was the best. To his mind, however, the clamp was, on the whole, likely to hold its ground.

Dr. Gardner, of Montreal, would, from his experience in its use, continue to employ the clamp.

Dr. H. Marion Sims, of New York, adopts the external method of treating the pedicle.

Dr. M. D. Mann, of Buffalo, felt that the extra-peritoneal method was a safe one.

Dr. Bantock closed the discussion, and said that thus far the rate of mortality was less with the extra- than with the intra-peritoneal mode of treating the pedicle in this operation.

Dr. Robert Battey, of Rome, Ga., then read a paper with the title,

BATTEY'S OPERATION—ITS MATURED RESULTS.

An account of his first operation was published in 1872. Mr. Tait had claimed some connection with Battey's operation soon after, in an alleged conversation with Dr. Chadwick, in 1873, which conversation the latter was unable to recall. He had performed the operation 54 times, with 33 cures. 8 much improved, 5 little improved, 8 not at all improved. There was complete menopause in 50 cases; continued pseudo-menses in 4. The prime object of the operation is to produce the "change of life."

Discussion was deferred until after the reading of a paper by Dr. A. W. Johnstone, of Danville, Ky., on

THE INFANTILE UTERUS.

This paper was of a histological and physiological character largely. One of the conclusions of the writer was that the uterus is not only an entirely independent organ, but that it embraces two parts whose functions are entirely separate, and that there may be arrest of growth in either or both. Another conclusion was that when life had become a burden that was clearly due to arrest of development, the menopause should be hastened, but not until it was certain that nothing else could give relief. He hoped that the uterus would be emancipated from the thraldom of the ovaries, in whose secure grasp it had been held during the last fifty years.

The discussion was opened by Dr. Sutton, of Pittsburg, who asked Dr. Battey two questions:

1. Are we to understand that Battey's operation is limited to removal of the ovaries?

2. Are we to understand that in 54 cases he removed the ovaries alone, and established the menopause in all but 4?

Dr. Battey replied that removal of the ovaries was not a necessary constituent of the operation. It was the *change of life* that he wished to establish, and not removal of ovaries.

Removal of the ovaries does not invariably produce the menopause, nor does removal of the ovaries and tubes, nor, still further, of the ovaries, tubes, and uterus.

Dr. Parvin, of Philadelphia, asked if the ovaries which Dr. Battey had removed were invariably diseased, and how frequently he found disease of the tubes?

Dr. Battey replied yes to the first question, and to the second that the ratio was small. As a rule, he removes only the ovaries, but the tubes when they are diseased—that is, cases of pyo- or hydro- or hepato-salpinx; he does not remove the tubes on account of a little blush along the surface.

The discussion was continued by Dr. Lloyd Roberts of Manchester, Eng.; Dr. Bantock, of London, Eng.; Dr. Polk, of New York; Dr. A. Reeves Jackson, of Chicago; Dr. A. R. Simpson, of Edinburgh, and Dr. Johnstone.

Dr. Theophilus Parvin, of Philadelphia, read a paper on

THE IMPORTANCE OF ANTISEPTICS IN PRIVATE OBSTETRIC PRACTICE,

in which he urged their use, and exhibited a very compact pocket-case which would facilitate the practical application of the principles involved in the method.

Dr. Aust-Lawrence, of Bristol, England; Dr. A. R. Simpson, of Edinburgh; Dr. W. L. Reid, of Liverpool; and Dr. H. N. Kelly, of Philadelphia, spoke of the benefits of antiseptic midwifery, and of the means of carrying it into practice.

Dr. Ely Van de Warker, of Syracuse, N. Y., then read a paper on

EXTRA-UTERINE PREGNANCY, AND ITS TREATMENT BY ELECTRICITY.

When the author of the paper read a recent contribution to this subject, in which it was stated that the five months' fœtus was completely absorbed within three weeks, after having been killed by electricity, he concluded that the elementary literature had not been made complete, and as a contribution to that end, he reported a case in order that the subject might be again discussed.

The sign which had seemed to him to be most reliable in deciding whether or not the electricity had done its work completely was *lessened tension in the cyst*, a sign more easy of detection than *shrinkage* of the tumor.

The paper was discussed by Drs. J. C. Reeve, of Dayton, O.; H. Marion Sims, of New York; James R. Chadwick, of Boston; A. Martin, of Berlin, who recommended removal of tubal pregnancy at once by laparotomy; Dr. Apostoli, of Paris, France; W. H. Baker, of Boston; M. D. Mann, of Buffalo; J. E. Janvrin, of New York.

The discussion was closed by Dr. Van de Warker, who thought it had been proved that galvanism was efficient in this class of cases, and that its use had been un-

attended with danger. He believed, however, that puncture or injection of the sac, according to Dr. Apostoli's suggestion, was even more dangerous than laparotomy.

THIRD DAY—AFTERNOON SESSION.

DR. FRANK P. FOSTER, of New York, read a paper on

VAGINAL INJECTIONS IN SIMS' POSTURE.

The main desiderata in the use of hot-water injections were the penetration of the water to a situation as closely contiguous as possible to the seat of the disease and its application in sufficient quantity at a time to secure the maximum action of the heat.

To answer these requirements he had lately employed the injections with the patient in Sims' posture, or rather in a posture somewhat more decidedly prone than the Sims.

The paper was discussed by Dr. Barker, of New York.

DR. CHARLES JEWETT, of Brooklyn, read a paper entitled

A NOTE ON THE TREATMENT OF PUERPERAL ECLAMPSIA,

in which he recommended the use of *veratrum viride* subcutaneously, in doses of from ten to twenty minims, and repeated at the end of half an hour if the pulse does not diminish in frequency. No convulsion can occur while the patient is under the influence of veratrum viride, and the pulse below sixty per minute. In no case has a dangerous prostration been noted. He does not advocate the *veratrum* as a remedy to be relied upon exclusively.

The paper was discussed by Dr. A. F. A. King, of Washington; Fordyce Barker, of New York, who was the first to introduce veratrum into New York nearly forty years ago; and the discussion was closed by Dr. Jewett.

RESOLUTION AND RESPONSES.

THE PRESIDENT, at this stage of the proceedings, said that the time was drawing near when adjournment of the Society must occur by limitation, and he believed that the remainder of the time could be devoted to matters which were not strictly scientific, but equally interesting.

DR. JOHN P. REYNOLDS, of Boston, then introduced a resolution, in which was expressed the thanks of the Fellows to the presiding officer for his wise, firm, and dignified conduct of the proceedings, to which the success of the meeting had been so largely due, and especially to express for the Fellows the feeling that the interest of that meeting, which had been so conspicuously marked in contrast with all former assemblings of the Society, had been due mainly to the delightfully kind part taken in it by their foreign friends.

Responses were made by Dr. Graily Hewitt, of London; Dr. A. R. Simpson, of Edinburgh; Dr. Lloyd Roberts, of Manchester, England; Dr. Balls-Headley, of Melbourne, Australia; and Dr. A. Cordes, of Geneva, Switzerland.

THE PRESIDENT replied that he could most heartily indorse all that had been said by the distinguished Fellow from Boston concerning the visit of their foreign brethren. He then made a few complimentary remarks, and introduced the President-elect,

DR. ROBERT BATTEY, of Rome, Ga., who returned his thanks for the great honor conferred upon him, and pledged his best efforts in behalf of the interests of the Society.

The Society then adjourned, to meet in Boston, on the *third Tuesday* in September, 1888.

OFFICERS FOR THE ENSUING YEAR.

President—Dr. Robert Battey, of Rome, Ga.

Vice-Presidents—Dr. James R. Chadwick, of Boston, and Dr. A. Reeves Jackson, of Chicago.

Secretary—Dr. Joseph Taber Johnson, of Washington.

Treasurer—Dr. Matthew D. Mann, of Buffalo, N. Y.

Other Members of the Council—Drs. Frank P. Foster, of New York; C. D. Palmer, of Cincinnati; James B. Hunter, of New York; and R. Stansbury Sutton, of Pittsburg.

New Members—Drs. Howard N. Kelly, of Philadelphia; H. T. Hanks and Bache McE. Emmet, of New York; and Cornelius Kollock, of Cheraw, S. C.

The proposition to become a part of the American Congress of Physicians and Surgeons was not adopted.

Correspondence.

LONDON, August 13, 1887.

LONDON is now supposed to be empty, it being in fashionable parlance "the dead season." It is only by a polite fiction that it can be described as such, for between three and four million people remain, including no inconsiderable number of doctors. Some of the latter have made the annual meeting of the British Medical Association in Dublin the occasion of a brief holiday in the sister isle, and are now returning; others are ruralizing within a short railway run of London, and come to and fro to look after their patients. The more fortunate are disporting themselves in Scotland, Wales, Ireland, the lake district, or the Continent, having left a locum tenens in charge. An efficient and steady locum tenens can easily earn three guineas a week, in addition to travelling expenses and board and lodging. Some few medical men gain their livelihood for years by taking charge of other medical men's practice. Employment is easily obtained through any of the recognized medical agents, and the work is not usually hard. In very small practices, or in those situated in very favored localities, much lower terms than the above are often offered and readily accepted—at any rate during the summer months. A consultant who ventures to leave his practice in the hands of a locum tenens usually pays the latter by giving him a proportion of the fees the latter receives. The share given will vary from one-half to one-fourth. At the latter rate the locum tenens receives of course five shillings and threepence for himself out of every guinea. I have known of one case in which the "locum" plaintively complained that in dividing the fees with him the physician for whom he was acting systematically omitted to give him the odd threepence due. A physician or surgeon in large practice will often leave word that he is to be summoned by telegraph to an important patient—even from the Continent. Those who envy physicians and surgeons in large practice little think of the physical toil many of the latter undergo in rushing about the country by train to see patients in all parts—sometimes travelling back to London through the night so as to see their patients as usual the following morning.

It being now the vacation season at the medical schools, lectures, etc., are in abeyance; but work in the wards and out-patient departments is going on. The months of August and September are, at most hospitals, devoted to cleaning, and some of the wards are closed in

rotation ; but the general work of a hospital goes on, as a rule, without intermission. The members of the staff take their holidays in turn. A goodly number of students, too, are now usually to be met with engaged in clinical work during the vacation. The old notion among students, that the moment they received their legal qualifications to practise they were fully equipped for their life-long battle with disease, has given way to larger ideas. Many now voluntarily continue their studies for a time after becoming qualified. Not only the hospitals attached to the schools, but others, and even many of the special institutions, are frequented by earnest students in search of information, and among them not a few young practitioners.

Clinical teaching in London has undergone a great process of evolution within the past decade. More and more, year by year, do teachers endeavor to avail themselves of all sources of clinical material. Even the workhouse infirmaries are now requisitioned for teaching purposes. It should be remarked, though, that these institutions are very different from what they were some years since, when Mr. Ernest Hart drew attention to their flagrant condition in a series of stirring articles in *The Lancet*, to which journal he was then attached. Dirt and disorder prevailed, and of skilled nursing there was practically none. One or two paupers, less infirm than the others, were set in charge of the others, and those helplessly ill had to be content with such attendance as they could get. Nowadays the arrangements are very different. The infirmary is now usually a separate building from the workhouse proper, and to it are relegated all those patients who are sufficiently ill to be confined to their beds. Many of the workhouse infirmaries are palatial structures, rivalling, in their architectural features and sanitary arrangements, some of the large hospitals. A sufficient number of paid nurses is provided, and they perform their duties under the watchful eye of one or more medical officers, who are debarred from private practice. It is not to be wondered at that, among the three or four hundred patients some of our workhouse infirmaries contain, many interesting and rare cases should be found. To some extent, as already mentioned, these clinical stores have already been utilized, but by no means exhaustively. There are great practical difficulties in the way. With such large numbers of patients under their care, the medical officers of such institutions already have their hands full of work, without adding to their other duties that of teaching. One proposal is to appoint outside medical officers as visiting physicians and surgeons ; but this plan is calculated to awaken jealousy in the residents, who naturally object to seeing others come in and utilize, for teaching and observation, just the very best cases they would like to reserve for their own study. I lately heard of a case in which an important hospital (one of such a size that I should have thought its staff were already overworked) actually proposed to appoint some of its staff to visit the neighboring infirmary with some of the hospital students and give instruction to them, without having even asked permission of the infirmary authorities to do so. Fortunately the plan was dropped, as it could scarcely have been carried through after such an unfortunate inception.

It is rumored that the President of the British Medical Association, Dr. Banks, is shortly to be created a baronet. I believe that Dr. Banks, a short time since, declined a knighthood, much to the gratification of his professional brethren, who thought the higher dignity should have been proffered to him.

The New Sydenham Society has just held its twenty-ninth annual meeting. As has been customary of late years, it has been held in conjunction with the annual meeting of the British Medical Association. Although it restricts its operations mainly to the issue of reprints and translations, the Society is in a flourishing condition, with a membership of more than two thousand. Among forthcoming works are translations of works and monographs by Spiegelberg, Raynaud, Klebs, Tommasi-Crudeli, Litzmann, Bandl, Charcot, and others.

This is the season of congresses. The British Association for the Advancement of Science will meet shortly at Manchester. Next month the Sanitary Institute will hold its tenth annual meeting at Bolton. Dr. Russell Reynolds, F.R.S., will be president of the Section of Sanitary Science and Preventive Medicine. If the collective wisdom of the Sanitary Institute could devise a means of improving the metropolitan water-supply, we poor Londoners should be extremely thankful. Until little more than a month ago, dwellers in house-boats and steam-launches (both of which abound on the upper river) have been allowed to throw overboard refuse of all kinds into the river just above the in-takes of the water-companies. After being permitted for years, this has now been forbidden and will, it is hoped, be put a stop to. But other equally bad sources of pollution remain.

London, August 19, 1887.

The Bradshawe Lecture for the present year was delivered at the College of Physicians yesterday by Dr. Samuel West, Assistant Physician to St. Bartholomew's Hospital. In the middle of August a very large audience could not be expected. The President, however (Sir William Jenner), was in his place and looked, I thought, remarkably well. Many of the leaders in medicine were also present, among whom might be noted Dr. Quain, Dr. Wilks, Sir Edward Sieveking, Dr. Munk, Dr. Powell, and many others. Dr. West took for his subject one which, he said, had been with him a favorite clinical study, viz., Pneumothorax. Of this he did not attempt any general account, but only discussed certain points. Phthisis, he remarked, was the chief cause and the primary lesion found in ninety per cent. of the cases. Many cases had been recorded in which pneumothorax occurred in the apparently healthy ; but, as in such cases recovery had always taken place, there had been no opportunity of proving or disproving the existence of a pulmonary lesion. Dr. West, however, opined that phthisis was present in many of these cases, and narrated some cases in point. He then considered the question of whether the healthy lung could be ruptured by any force brought to bear upon it by respiratory efforts. This question was answered affirmatively, though it was at the same time pointed out that violent expiratory efforts much more commonly produced subcutaneous emphysema than pneumothorax. Some experimental researches, made with a view of determining the pressure on the air-cells of the lungs at which rupture occurred, were then detailed. Dr. West's results agreed with those of Hutchinson, who had found that the air-cells could resist a pressure of from three to nine inches of mercury when expanded as in health. Most of his own observations were made upon the lungs after removal from the body, and he remarked that the bursting pressures thus obtained were no doubt much below those required with the lungs *in situ*. In the only instance in which he had attempted the experiment upon the dead body, the air did not appear in the neck until a pressure of eight inches of mercury was registered ; on examination, pneumothorax was found to have been produced on both sides. A pressure of eight or nine inches of mercury was far beyond anything that an adult could produce by expiratory effort. It was clear, therefore, that it could only be in cases where the normal resistance of the lung had been greatly reduced that (in the absence of any pulmonary disease) pneumothorax could be produced. The lung being thus in most cases capable of resisting the highest pressure that the most violent expiratory efforts could bring to bear upon it, the question might well arise, in those cases where the lung gave way, whether the absence of a local lesion could be without hesitation assumed ? It was a remarkable feature of many cases occurring in the apparently healthy, that there was fre-

quently a complete absence of any history of respiratory effort. The lecturer then proceeded to consider those cases of pneumothorax in which the pleural cavity had been laid open by injury. He quoted a passage from "Foster's Physiology," in which the mechanism of pneumothorax is described as consisting in the shrinkage of the lungs (by their own elasticity), whereby the pulmonary is drawn away from the parietal pleura. This explanation Dr. West proceeded to confute. There were, he said, not a few instances in which, in spite of the pleura being opened, collapse did not occur. In some cases where the side of the chest had been laid open, the lungs—although seen torn and bleeding in the wound—remained in close apposition to the thoracic walls, and no pneumothorax was produced. Cases in which, without any external wound, the lungs were torn and the pleural cavity opened were still more interesting. In cases of simple fracture of the ribs, with surgical emphysema, it was clear that both layers of the pleura were torn across and the lung opened, from the fact of air having made its way into the subcutaneous tissue; yet pneumothorax in these cases was extremely rare. Various explanations had been offered, but Dr. West now put forward a new one, viz., that in such cases the cohesion of the two serous surfaces kept them in contact. Accepting Donders' estimate of the normal elasticity of the lung as equivalent to seven millimetres of mercury, it followed that when the lung did not contract after the pleura was opened it must be kept on the stretch by some force greater than seven millimetres of mercury. He held that this force was to be found in the cohesion between the two serous surfaces of the pleura. He had investigated the point experimentally by taking two mahogany disks, stretching over them tightly pieces of serous membrane with the serous surfaces outward, and, after placing these surfaces in contact, observing the force required to separate them. This was found to be equal to twelve and a half millimetres of mercury, or five and a half millimetres in excess of the equivalent of the normal elasticity of the lung. (The cohesion of the disks was not due to atmospheric pressure, as air was admitted between them by means of an opening.) A more exact form of the experiment gave a still higher value to the force of cohesion. He found this cohesive force was destroyed by wetting the membrane, and equally by absolute dryness; the surfaces must be simply moist, as normally in healthy pleura. Any roughness of the membrane also prevented cohesion.

The variations of pleural pressure were then considered at some length. It was pointed out that the displacement of organs, especially of the heart, was the most important result of these variations. The heart, when displaced, was not, as once supposed, rotated, but simply drawn or pushed bodily over. The prognosis of pneumothorax was briefly discussed, and attention directed to the high mortality of cases occurring in the ordinary course of phthisis. In cases in which recovery occurred this might take place in one of two ways: The pneumothorax might become converted into a case of fluid effusion which healed in the usual way, or the air disappeared without the development of any fluid at all. In the first group of cases the exudation was usually, but not invariably, serous. The second method of recovery was much rarer. Rapid removal of air was familiar in experimentally produced pneumothorax, it being in fact difficult to maintain an artificial pneumothorax long in a healthy animal, because the air so quickly disappeared. Fluid effusion might also in like manner be rapidly removed. In both cases the lung might rapidly re-expand. The lecturer remarked that the common explanation of this re-expansion was not satisfactory. In the case of fluid the question was simpler than in the case of air. Fluid might be removed in many ways—by absorption, by transudation, or by the pump-like action of the respiratory movements upon the lymphatics of the pleura. He regarded the latter as an important factor. It depended upon the demonstration of stomata in the parietal and visceral layers of the pleura. To this mechanism was due the favorable result frequently brought about by removing a part of the fluid by paracentesis. Paracentesis was followed by a return of the respiratory movements, which had been more or less impaired by the large effusion, and as a consequence the lymphatic pump would be restored to action. Experiments showed also that a still air-tight lung was permeable to fluid under pressure, so that it was possible that a part of the exudation might be actually squeezed through the lung as through a sponge, and, when it had reached the bronchi, might be got rid of partly by expectoration and partly by absorption. The removal of gases was a more complicated problem. It might be brought about by diffusion, by simple absorption, or by absorption aided by chemical combination. The latter was considered somewhat fully, the variations in the chemical composition of the gases of pneumothorax, of the lungs, and of the blood being discussed, and some ingenious speculations offered. The general conclusion was drawn that in many of these processes there were sources of power sufficient to provide the force of which we were in search. Dr. West illustrated his lecture with several experiments, all of them being very successful, offering a happy contrast to many lecture experiments.

An important step is now being taken to organize the Volunteer Medical Service. The Volunteer Medical Association has had amalgamated with it the Volunteer Ambulance Department, the former title being retained for the conjoined bodies. An effort is being made to induce every volunteer medical officer to join the association. It has already done useful work in pushing forward on the government the claims of volunteer medical officers, and with its enlargement a larger sphere of usefulness promises to open out before it.

An institution has just been founded under the title of "The College of State Medicine." Its objects are the advancement of sanitary science. The acceptance by Sir Joseph Fayrer of the office of president is almost in itself a guarantee of success.

The question of university education in London still drags wearily along. University and King's Colleges have presented to the Privy Council their joint petition asking for powers to confer degrees. The association for promoting a teaching university have presented one similar in purport. That from the Colleges of Physicians and Surgeons has not yet been sent in. Meanwhile numerous counter-petitions have been presented. Not only the existing university in London, but four other universities, have taken time by the forelock, and lodged objections to the creation of a fresh degree-giving body.

LONDON, August 30, 1887.

BEFORE these lines are printed in your pages, the Ninth International Medical Congress will be an event of the past, and we shall be looking forward to its successor. In a certain sense we have already reached that stage here, for, as the Congress commences in less than a week from now, all those from Europe who intend taking part in it must be already well on their way. The British contingent will, I fear, be but a small one, and not equal in numbers to that which came from the States to take part in the Congress held here in 1881. The reasons are not far to seek. They imply no unwillingness to recognize the claims of American medicine nor any distrust of American hospitality. One drawback is the date of the Congress, which is fixed somewhat late in the season. Europeans attending it will scarcely be able to reach home much before October. It must also be confessed that Englishmen are not such travellers as Americans. Many English doctors also have neither the time nor the money to devote to spending a month on the Congress. I suppose this is the minimum time any of those who have gone from this country will be absent. Nevertheless, those who are unable to go will none the less be interested in it, and will look forward with zest to

the full and faithful reports of its proceedings, which are sure to appear in THE MEDICAL RECORD and other journals.

We have hitherto escaped the almost inevitable cholera scare, though one or two isolated cases have been reported as occurring. Scarlet fever, however, is justifying its name of the "English fever," by being unusually prevalent in London and the suburbs. The proportion of fatal cases, however, appears to be much less than in former years. This may in part arise from increased attention to the disease on the part of medical men, nince what may be termed the bacillary era came in. Sumbers of observers—both skilled and unskilled—have been on the alert to discover any fresh fact in relation to any one of the specific infectious fevers. So far as medical education goes, fevers have been as much neglected as mental diseases. Plenty of our students never see a case of measles or scarlet fever till after obtaining their qualifications. The ordinary hospitals refuse to admit such cases, though, of course, cases sometimes develop among the patients already received. In the out-patient departments infectious fevers occasionally turn up. For any real study of these diseases, however, the student has to wait for the opportunities of private practice, un less he can get the chance of doing a little visiting among dispensary or poor-law patients. There is, it is true, one fever-hospital in London, but it is not utilized for teaching purposes. The various hospitals of the Metropolitan Asylums Board also receive fever-patients, but the same remark applies to them. They are supported mainly for isolation-purposes, in which they serve a very useful purpose. It is now very common for practitioners to send poor patients to these hospitals for isolation-purposes, even if not absolutely paupers. Such patients are admitted on making a moderate payment. In the case of variola, the friends are often only too glad to send the patient away. One consequence of these facilities will undoubtedly be that in a few years a general practitioner with much experience of variola or typhus will be a *rara avis*.

One noteworthy feature of the celebration of the Queen's Jubilee here was the Women's Jubilee Offering. This consisted of *money*, and formed a good round sum. Some of it has already been spent by the Queen on a statue of the Prince Consort, etc., but nearly seventy thousand pounds, or two hundred and eighty thousand dollars, remain. Numerous have been the conjectures as to what the Queen would do with it, but no light was obtainable on the subject. After two months' consideration Her Majesty has at last announced that the surplus left will be donated to nursing institutions, or otherwise expended for the benefit of nurses.

The spleen has hitherto been an organ somewhat overlooked by specialists, no one having, I believe, as yet ventured to couple his name with it as an authority on its diseases. Physiologists have been busy enough discussing it. Some ten years or more ago a curious pamphlet on the subject, from the pen of one of the physicians to St. Bartholomew's Hospital, appeared under the title of "The Marriage of the Spleen: a Physiological Love Story." A physician for the spleen has, however, at last arisen, for I note in the advertising columns of *The Standard* for today, an announcement of a work on "Diseases of the Spleen and their Remedies, clinically Illustrated. By J. Compton Burnett, M.D." Splenic diseases evidently possess no terrors for Dr. Burnett. The object of advertising his work in a daily newspaper is somewhat dubious. Is it to bring practice, which is one of the real objects of advertising, though not often openly acknowledged to be? If so, how are patients to be first taught that they have a spleen, and then persuaded that it is diseased? But perhaps the author's aim is strictly scientific, though I should scarcely have thought a daily paper was the best medium for reaching a strictly medical audience.

Medical advertising is a vexed question. It is considered by the medical Mrs. Grundy quite allowable to advertise a medical work in the "publishers' column" of *The Times*, such column being restricted to new books of the current three months. To insert an advertisement in the ordinary literary columns of the same paper is, however, quite another matter, and to do so in one of the penny dailies a most reprehensible proceeding! Yet why is one column of a newspaper worse than another, and why is it disreputable to insert in a penny paper the same advertisement that appears without comment in a threepenny newspaper?

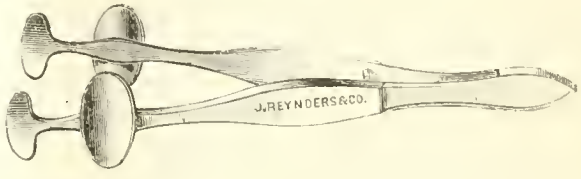
New Instruments.

THE TRACHOMA-FORCEPS.

By CHARLES H. MAY, M.D.,

NEW YORK.

THE accompanying cut is intended to illustrate a forceps designed to aid in the use of the *expression-treatment of trachoma*. This method of treatment (pressure) is based upon rational principles—of getting rid of the trachoma-follicles by pressing out their contents, and thus having collapse and obliteration of the granulations. But though made use of by some, notably Hotz, of Chicago, it has not gained a strong foothold with the majority of oculists. This is because it has been tried and found to possess no advantages over the old-established copper-treatment; in fact, most oculists consider it inferior to the latter method of treatment.



The writer, in having these forceps constructed, did so with the hope that, with a better method of applying expression, this plan of treatment might be productive of uniformly better results than followed the older methods, which, at best, are often lengthy and tedious. The usual method of producing the pressure necessary for emptying the trachoma-follicles is to evert the upper lid, to pass underneath it the nail of the left thumb, and upon this smooth, resisting surface to exert pressure by means of the nail of the right thumb. This plan is sometimes difficult of application, especially if the procedure is to be thorough. Dr. Hotz, of Chicago, uses an "old-fashioned" iris-forceps for this purpose.

The trachoma-forceps accomplishes expression as thoroughly as can be desired.

It consists of a forceps resembling, in the main, the ordinary dissecting-forceps. They are provided, a short distance from the lower extremity, with rests for the fingers in exerting the pressure, which also renders the roughening of the surfaces unnecessary, and thus allows the instrument to be kept perfectly clean. The lower extremities present two nail-like expansions, each about one-third of an inch wide, and having a curve resembling that of the lids. In applying them, one blade is inserted beneath the everted upper lid and the other above the lid; by exerting force upon the lateral finger-rests, pressure can be made to a greater or less degree. To use them upon the lower lid they should be applied vertically, the palpebral fold being caught between the two blades, and, by pinching, the granulations are emptied.

As already hinted at, the writer's experience with the expression-method of treating trachoma has led him to believe that it is *inferior* to other methods now in use. But there is one ocular condition in which these forceps are of immediate service and very gratifying in their results. In cases of *trachomatous pannus*, where a thickened, angry-looking upper lid causes, by the space occu-

pied and mechanical crowding, intense irritation of the cornea and marked suffering, the action of this instrument, in immediately reducing the thickness of the lid, is very satisfactory. There is comparative comfort at once, and then the routine treatment for trachoma can be instituted. From time to time, as acute exacerbations occur, and increased thickness of the lid results in increased irritation to the cornea, the procedure should be repeated. The operation is not very painful, and can be rendered less so by the use of cocaine. Used in this manner, and *for this particular indication*, the expression-treatment of trachoma gives highly satisfactory results.

202 East Fifty-eighth Street,
April 25, 1887.

Navy News.

Official List of Changes in the Medical Corps of the United States Navy for the week ending September 17, 1887.

Ashbridge, Richard, Passed Assistant Surgeon. Detached from the Constellation, and ordered to the Naval Academy, Annapolis, Md.

Ayers, Joseph G., Surgeon. Detached from Torpedo Station, and to await orders.

Wise, John C., Surgeon. Ordered to relieve Surgeon Ayers at Torpedo Station.

Coues, Samuel T., Medical Director. Detached from Hospital, Chelsea, Mass., and placed on retired list September 17th.

Bradley, George P., Surgeon. Leave of absence extended six months, with permission to remain abroad.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 17, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	47	11
Scarlet fever	26	6
Cerebro-spinal meningitis	1	1
Measles	7	1
Diphtheria	76	24
Small-pox	6	3
Yellow fever	0	0
Cholera	0	0

A Rare Dislocation of the Patella.—Dr. V. Midelfart relates in the *Norsk Magazin for Lægevidenskaben*, July, 1887, the case of a twelve-year-old boy who had fallen some days before against a sharp stone. There was apparently a transverse fracture of the patella. The lower fragment was immovable, while the upper one could not be felt, but by pressing the finger forcibly upward and backward a slight crepitation could be obtained. The knee had been first flexed and then extended, and it was thought that perhaps the upper fragment of the patella had been torn from its attachment to the quadriceps and had become lodged between the articular surfaces of the femur and tibia. The joint was opened, and it was then found that the patella was not broken, but was dislocated, its upper edge lying against the articular surface of the tibia and its lower portion projecting strongly forward. The latter was what was supposed to be the lower fragment immovably fixed. The tendon of the quadriceps had been torn from the upper anterior surface of the patella, carrying with it some fragments of bone, which had occasioned the crepitus elicited by deep pressure with the finger.

A New Local Anæsthetic.—Dr. G. W. Durham, of Thomson, Ga., writes: "In your issue of July 30th the attention of the profession is called to a new anæsthetic by Drs. Goodman, V.S., and J. Herbert Claiborne, Jr. As to the medicinal virtues of the tree I know nothing; but if I am not very much mistaken, Professor Darby, in his 'Botany of the Southern States,' describes it as Gleditschia triacanthos. The tree is common throughout the Southern States, and in rich soil attains to the height of fifty or sixty feet. It is commonly known as sweet, or honey, locust. The fruit is highly esteemed by most of the negroes for making beer. The wood is highly esteemed by wagon-builders. It is very tough and very slow to decay, hence it makes extra hubs."

Genealogy of Neurotic Families.—Dr. M. J. Séglas laid before the Medico-Psychological Society of Paris (London *Medical Record*) the genealogy of two neurotic families in which at least twelve members out of thirty-four were deranged in mind. The following sentences contain a conclusion which he is anxious to impress: It has been often remarked that persons with a neurotic heredity often intermarry; this is now generally admitted. What explanation can be given? Are these unions simply the result of chance, or of different social causes (family reasons, considerations of fortune), or are they dictated by a sort of fatality, or natural law? In admitting the possibility of other causes (and it is this which renders the question so difficult) it is insufficient to explain the innumerable cases of convergent heredity, observed by the doctors in all times and countries, and which are only the result of these fatal unions. On the other side, the illegitimate unions which present characters precisely similar are not to be explained by all these particular causes, and are more demonstrative of the fact upon which we insist. Besides, the repetition of the same facts in a single family, in the same generation, and in the following generations, in nearly all the members of these generations, and sometimes even several times in the life of the same individual, seems to us to be a proof of what we advance. In the particular case which we report, this unhealthy attraction which draws persons with neurotic tendencies to each other by a sort of community of ideas and sentiments is the most manifest. It is found again in all the generations, in all the members of each generation, and even several times in the same individual. We find in it also consanguinity, which is on this account the more demonstrative. Moreover, these unions between blood-relations are not rare, and thus create a convergent heredity of the worst description in the descendants.

Dysacusis.—M. Lannois has published an article on hyperacusis in facial paralysis, and on the influence of mastication on the acuity of hearing. Among some individuals a very notable diminution of the faculty of hearing may be detected during mastication, and this diminution may even amount to actual deafness, so that on addressing the masticating individual not a syllable reaches his consciousness. In some cases of facial paralysis a distressing sensation in the ear of the paralyzed side may be experienced, and this has gone incorrectly by the name of hyperacusis. The tensor tympani or internal muscle of the malleus receives its nerve-supply through a small branch from the otic ganglion on the third part of the fifth nerve. It is held, therefore, that in paralysis of the facial nerve the auditory phenomenon is due to concomitant paralysis of the stapedius, which is believed to be supplied by the facial nerve, but this nerve does not supply the tensor tympani. The diminished auditory capacity observed in some individuals during contraction of the masseter and other muscles supplied by the motor part of the fifth nerve, is the result of a simultaneous but too energetic contraction of the tensor tympani, which is innervated motorially by the fifth nerve also.—*The Lancet.*

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 32, No. 14. NEW YORK, OCTOBER 1, 1887 Whole No. 882

Original Articles.

GLEDITSCHINE (STENOCARPINE), THE NEW LOCAL ANÆSTHETIC.

BY J. HERBERT CLAIBORNE, JR., M.D.,

INSTRUCTOR IN OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC, CLINICAL ASSISTANT IN THE VANDERBILT CLINIC, ETC.

THE *Gleditschia triacanthos*, or thorny locust, is the tree from which the new local anæsthetic, discovered by Mr. Goodman, is obtained.

This conclusion has been reached in the following wise :

Soon after making the experiments recorded in my first article on this subject in THE MEDICAL RECORD, I searched all the literature afforded by the Astor Library relative to the American flora.

The description of the tree given by Mr. Goodman exactly corresponded to that of the *Gleditschia triacanthos* as found in the authorities mentioned. Just at this time a letter was received from Dr. W. P. Copeland, of Eufaula, Ala.; therein it was stated that in his opinion the tree could be none other than the honey-locust. At my request Mr. Goodman sent home for some of the leaves. After some delay leaves were forwarded, which were not recognized as those from which the anæsthetizing principle was extracted. Another order, more explicit, was given. In the meantime a communication, addressed to Professor F. W. Snow, of the University of Kansas, relative to the tree, elicited a very courteous reply.

Professor Snow recognized in the description given by Mr. Goodman the *Gleditschia triacanthos*, or honey-locust.

The second batch of leaves from Louisiana having been received, specimens of the leaflets were forwarded to Mr. Sereno Watson, of the Harvard University. He stated that from the scanty specimens sent he could conclude only in favor of the *Gleditschia triacanthos*.

Dr. L. P. Walker, of this city, said that he recognized in the description the thorny locust of his native State, Alabama, and that the tree could be found in great abundance in Central Park. Under his direction I found several clumps of the tree there.

Unsatisfied, I requested Messrs. Goodman and Seward to accompany me to the Park. A clump of trees was recognized by them as being identical with the one from which they had obtained their leaves, save that the trees in the Park did not possess any pods, whereas those in West Feliciana Parish, La., did. A branchlet of one of the clump in the Park, recognized by these gentlemen, and leaflets, pods, and spines of the specimen sent Mr. Goodman from Louisiana, were presented to Dr. H. H. Rusby, Curator of the Herbarium of the Columbia College, New York. He recognized them as identical, and the tree as the *Gleditschia triacanthos*, or thorny locust.

A letter addressed to the Tulane University of New Orleans remained unanswered for some time, owing to the absence of the Professor of Botany. Finally, a very full answer was received from Professor Jos. F. Joor, M.D., Professor of Botany in said institution.

Professor Joor stated that the description given by Mr. Goodman *exactly* tallied with that of the *Gleditschia triacanthos;* but that the name "Tear-blanket-tree," was applied locally to various prickly trees and shrubs, chiefly Texan and Arizonian, and that one of these was the *Acacia* (Vachellia) *farnesiana*, which grows along the Mississippi, between Baton Rouge and New Orleans; that he had never heard the name "Tear-blanket" applied to any tree indigenous to Louisiana. He stated, however, that the *Acacia farnesiana* never grew over seven or eight feet high in Louisiana, possessed *white* spines that were straight and *unbranched*, and bore a pod that corresponded in no respect with the one described in my article.

He would, however, make inquiries if I requested. This was earnestly suggested immediately by letter.

The last link in the chain of indisputable evidence was furnished by a telegram from Professor Joseph F. Joor, stating that "*Gleditschia triacanthos* is correct beyond peradventure."

FIG. 1.

At the dictation of Dr. H. H. Rusby I wrote the following :

"Gleditschia, Genus; Natural Order, Leguminosæ; occurs in temperate and subtropical Asia and North America. Consists of four or five species; there are two in this country, which are quite readily distinguishable one from the other.

"*Gleditschia triacanthos* Linn. has a long pod with a number of seeds in it. The pod may be straight, sickle-curved, or even twisted spirally.

"*Gleditschia monosperma* Walt. has a short pod containing but a single seed, or very rarely two.

"In this section leaves are deciduous, the tree being bare in winter. It is said that along the Gulf the leaves persist during the winter.

"Inasmuch as it has been stated (by Dr. Seward) that the winter leaves in Louisiana contain a larger amount of the alkaloid than the summer ones, it is possible that in this section, where the leaves never reach the winter

stage, they may be much less rich in alkaloidal properties."

From "Gray's Botany," last edition, I quote the following:

"Gleditschia Linn. Honey-locust. Flowers polygamous. Calyx short, 3–5-cleft, the lobes spreading. Petals as many as sepals, and equalling them, the 2 lower sometimes united. Stamens, 3–10, distinct, inserted with the petals on the base of the calyx. Pod flat (G. T. many-seeded). Seeds flat. Thorny trees, with abruptly once or twice pinnate leaves and inconspicuous greenish flowers in small spikes. Thorns above the axils.

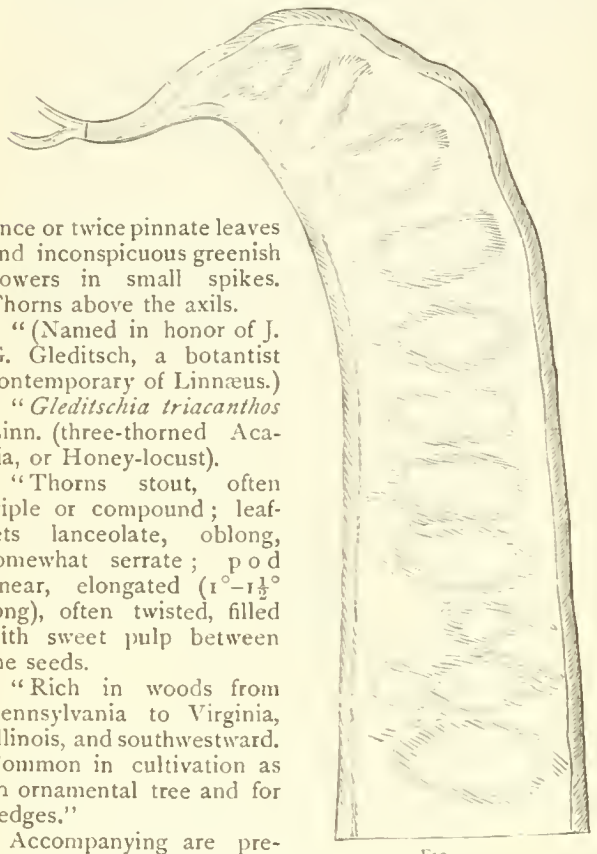


Fig. 2.

"(Named in honor of J. G. Gleditsch, a botantist contemporary of Linnæus.)

"*Gleditschia triacanthos* Linn. (three-thorned Acacia, or Honey-locust).

"Thorns stout, often triple or compound; leaflets lanceolate, oblong, somewhat serrate; pod linear, elongated (1°–1½° long), often twisted, filled with sweet pulp between the seeds.

"Rich in woods from Pennsylvania to Virginia, Illinois, and southwestward. Common in cultivation as an ornamental tree and for hedges."

Accompanying are presented cuts of the leaf, spines growing from a branchlet, and a part of one of the pods.

The leaf and branchlet from which the cuts were drawn were clipped from one of the group of trees in the Park, recognized by Drs. Goodman and Seward.

The clump above referred to did not possess any pods, as stated.

The one from which the cut was made was taken from a tree in the vicinity. Leaf and spines are of the natural size, while only a part of the pod is shown. This was ten inches in length and curled upon itself. This curling is not shown in the figure.

If anyone be sufficiently curious, he may find a clump of the thorny locust just to the right of the bear-pit in the Park; or he may find a hedge of the thorny locust skirting the wall facing on Fifty-ninth Street, between the Broadway and Sixth Avenue entrances to the Park.

According to Dr. Rusby, there is no reason to assume that the thorny locust and honey-locust are not identical. Certain it is that the pods of some trees contain a sweet, viscid juice, and that those of others do not. In my native section, the eastern part of Virginia, the name wild locust is applied to those trees whose pods do not contain any juice, and honey or domestic locust to those that do.

As a boy I have frequently eaten the juice of the honey-locust, and considered it a great delicacy. I have never observed any unpleasant after-effects. The fruit is not considered edible till it has been nipped by frost.

Dr. Copeland writes me that as a boy he has experienced an unpleasant sense of intoxication after eating freely of the pods. It has been stated in a recent issue of the *Times-Democrat*, by Dr. Phares, of Louisiana, that the juice has been used in that State to make beer.

It would be interesting and pertinent to observe that the active principle was reduced on the banks of the Mississippi, in the vicinity of the tree from which the first poultice was made. Dr. Seward and Mr. Goodman inform me that the simplest domestic utensils were used.

Mr. Goodman has just written me that "the new alkaloid is not, strictly speaking, a powder, but a semi-liquid mass, of a greenish tint."

Dr. Seward tells me that the leaves were treated before they became dry, and that he was not able to extract the alkaloid from them after they had dried.

All the solution of the alkaloid at present possessed was made before leaving Louisiana. Only a few leaves, spines, and pods of the tree had been brought to New York, hence my desire for accurate specimens had to remain for a time ungratified.

This historical notice would be incomplete, if I failed to express my thanks to the gentlemen who have assisted me in presenting the foregoing facts to the medical public. I wish to express my sense of gratitude to Dr. Copeland, Dr. Walker, Dr. Rusby, Professor Joor, Professor F. W. Snow, Mr. Sereno Watson, and to my friend Mr. W. T. Thatcher, by whom the drawings were made.

We have abundantly corroborated the statements made in our former article with reference to the effects of the alkaloid on the eye and nose. No operations other than that of removal of foreign bodies from the cornea have been performed under its influence. The irregular dilatation of the pupil of the treated eye we have observed so constantly that we deem it worthy of repeated record, although it may not have any peculiar significance.

The contraction of the opposite pupil has occurred sufficiently often for us to be compelled to note *it* again. A diminution in tension when the mydriatic effect was at its height, we have noticed in every case since our former report. The eye of the rabbit, upon which our first experiments were made, presented a dry and glazed appearance, similar to that produced by cocaine. This has not been observed in any case on the human eye; the latter class of eyes have invariably remained humid under its use. In testing the anæsthetic effect of the drug on the cutaneous surface, five or six drops of a two per cent. solution were instilled upon a small piece of absorbent cotton; after this had dried it was removed and placed in a two-drachm bottle that had formerly contained some of the two per cent. solution; one drachm of hydrant water was poured into the bottle, shaken well, and allowed to stand for an hour. Two drops of this were instilled into a patient's eye; there was no such recoil as is often observed from the instillation of the two per cent. solution. In five minutes the conjunctiva and cornea were completely anæsthetic, and remained so for twenty minutes. At the end of an hour the pupil was dilated almost *ad maximum*.

This solution has been used in a number of cases, and always with the same result. A calculation has been made of the percentage of this solution; supposing that none was lost on the skin the strength cannot be more than one grain to the ounce of water (one-fifth of one per cent.).

This indicates a very remarkable power. The bleaching of the conjunctival vessels was marked; more so, we must confess, than under the effect of a two per cent. solution. The palpebral fissure was rendered by no means as great as by the two per cent. solution. From these facts we may infer that the latter solution is not necessary to cause anæsthesia in the eye.

We have obtained the most brilliant results, therapeutically, by its use, in relieving the pain of iritis and the photophobia of trachomatous pannus and phlyctenulæ. For these purposes it is eminently indicated, since it combines the action of atropine and cocaine. Unfortunately no case of glaucoma has fallen into our hands since we have been in possession of the drug. One pair of glasses

had been prescribed under its use. The case was one of compound myopic astigmatism in which there was a severe spasm of the accommodative muscle.

On the first morning five drops were instilled into each eye within a period of three hours. The patient complained at one time of dryness of the throat. This was relieved by drinking a little water. At the end of three hours the patient could only read the larger prints of Jaeger's test-book within his far point, but, owing to a lack of uniformity in the results gotten by the functional examination, I suggested that he return on the morrow. On that day five more drops were instilled into each eye. In three hours the results of examination by the functional method, retinoscopy, and the direct method tallied. On the morning of the fifth day the pupil and accommodation were normal. The examination now corresponding with that under the use of the drug, the glasses were prescribed and relief was given.

Fig. 3.

The dilatation was never any greater than that obtained from two drops in other cases, and the effects passed off equally as rapidly.

In order to determine the influence of eserine over a pupil, and accommodation under the effect of the alkaloid, I had one drop instilled into my left eye. As soon as the mydriatic and paralyzing effect became evident, frequent instillations of a solution of the sulphate of eserine (gr. ¼–f ʒ j.) were made. After a few minutes the eserine would enable me to overcome the effect on my accommodation, and I would be able to read with an effort for a short time. The pupil would become somewhat smaller, but never, on the first day, returned to its normal size. For several hours before retiring the instillations of eserine were discontinued, and at midnight the pupil was practically dilated *ad maximum*, and the accommodation completely paralyzed. On the following day both pupil and accommodation could be managed by frequent instillations of the eserine, but the change of the accommodation and the pupil did not keep pace; in fact, at one time the left pupil was rendered smaller than the other, while I was able to read only Jaeger's number five or six at ten inches.

It has been employed in a number of cases of acute myringitis, and in acute middle-ear catarrh associated with myringitis.

In a case of the latter, where the drum was excessively swollen and bulging, the external auditory canal was half filled with the solution, and it was allowed to remain half an hour; paracentesis was performed in the lower and posterior quadrant, the Schwartze incision being made. The patient seemed to suffer the utmost pain; evidently *no* anæsthetizing effect was produced.

In numerous cases of the above affection in which the drum was greatly reddened, a few drops allowed to rest on the drum caused evident bleaching, so that the vessels that ran over the drum from the periphery, which were very marked before the instillation, could scarcely be seen. These cases all improved under treatment. In view of this effect, we feel warranted in suggesting it as an indication in the two affections mentioned. One patient complained of a "numb feeling in the ear." We have not used it at all in purulent middle-ear disease.

In our former report we settled the anæsthetic effect upon the nose, through the assistance of Dr. L. P. Walker. This experience has been amply verified in my own case and in that of a patient. Some of the two per cent. solution was freely painted on the exceedingly swollen mucous membrane of the inferior turbinated bone of a young man. In five minutes the swelling had entirely disappeared, the mucous membrane clung closely to the bone, and was rendered pale. Tactile sensibility was entirely eliminated.

Suffering from a severely acute attack of coryza, I painted with a cotton-armed probe the whole of the interior of my anterior nares on both sides with the solution. In ten minutes my breathing was perfectly free, and all sensibility to touch in the nose was removed. The entire organ felt deadened—not unlike the sensation produced by frost-bite. This remained, gradually diminishing, for three hours. The coryza was completely relieved until five or six hours after treatment, when it returned slightly. Another application before retiring relieved it entirely.

I have frequently had cocaine applied in the same way in stronger solutions, and can safely say that the anæsthetic effect of Gleditschine is decidedly more profound and lasting than that of cocaine.

Dr. Knapp has obtained anæsthetic effect upon the throat and the other mucous surfaces of the male human body, under its use.

With reference to the effect upon the skin, our results since our former report have been somewhat contradictory. We have applied it twice ourselves to inflamed surfaces in the manner first employed; that is, by saturating a piece of absorbent cotton with it and allowing the cotton to remain twenty to thirty minutes on the part. In each case there was decided evidence of pain when the incision was made. Bearing in mind the pathological condition by which the nerve-filaments are surrounded in inflammation, we were not sanguine of success in these cases. My friend, Dr. George T. Harrison, applied it in the manner suggested by myself, in a case of ingrowing toe-nail. He states that in his opinion the pain of the operation was considerably diminished. It was attempted to remove a chalazion (fibroid tumor) from the upper lid of a man thirty-five years of age, under its use. The cotton, saturated with the solution, was laid on the skin covering the tumor and allowed to remain thirty-five minutes. At the end of that time a small incision was made in the skin over the seat of the tumor. The patient complained bitterly both of the incision and the consequent manipulation. Soon after the publication of Dr. Knapp's article, in which it was stated that absolutely no anæsthetic effect was observed under its use on the unbroken cutis, Mr. Goodman brought me another sample of the solu-

tion. I immediately noticed that this was colorless and possessed scarcely any smell, while the taste, though like that of my first sample, was less pronounced. He stated to me that the first sample, with which I had obtained anæsthetic effect upon the skin, had been preserved with salicylic acid; that which Dr. Knapp had used, with boric acid. He then dissolved some salicylic acid in a solution of the alkaloid which had already been prepared with boric acid, and noticed that a gummy sediment was precipitated. He then filtered the supernatant fluid till it became perfectly clear. This was brought to me and used on the patient with chalazion. Several days after I received it, a few beads of some deposit were discovered on the sides of the bottle. This was examined under the microscope. There was no evidence of fungoid growth, and, judging from the stringy nature of the sediment when disturbed with a platinum needle, it has been presumed that it is the same gummy substance which was observed by Mr. Goodman.

The odor and taste of the solution have invariably increased with age.

The solution which failed to give anæsthesia in the case of the man with the chalazion, I used on my own person seven days later. Its anæsthetic effect upon my own cutis has been unequivocal equally satisfactory with that obtained by the first experimentation mentioned in my former article.

With this same solution we have just obtained complete anæsthesia on the inner surface of a rabbit's ear in seven minutes. Puncture of the ear in the vicinity not touched by the solution was followed by vigorous struggles from the animal.

It is impossible for me to explain these facts; I consider it my duty, however, to record them as they are.

I feel confident that all observers will finally agree on this point—in favor of its anæsthetizing effect on the unbroken, uninflamed cutis.

Dr. Knapp has experimented with the alkaloid, with reference to its systematic effect, by hypodermic injection in rabbits and in man.

I have taken a number of doses by the mouth. Below are recorded the effects observed:

Five drops of a two per cent. solution (about one-ninth of a grain) have been taken three times. On the first occasion my pulse, which is usually between 75 and 80, went up, just before taking the dose, to 98 beats per minute, owing to excitement. In half an hour the pulse was still 98, but fuller and stronger. In three hours it had fallen to 66, was stronger in general than before taking, but was somewhat irregular in force and rhythm. On the other two occasions of taking five drops the pulse fell 18 and 20 beats in two or three hours. The effect on its character as to force and rhythm was the same as after the first dose.

A slight sense of constriction in the soft palate persisted fifteen minutes after each dose. A sense of well-being and surface-glow was experienced; there was also invariably slight drowsiness; these symptoms wore off in several hours, and left me with a dry throat and husky voice, which persisted two or three hours.

On one occasion five drops were taken, and three hours afterward eight more drops (about one-fourth of a grain in all). In one hour the additional eight drops reduced the pulse only 6 beats lower than five had reduced it.

Five drops were taken, and repeated in an hour; two hours and a half after the first dose the pulse had fallen 18 beats. After all doses it recovered its normal beat and character in from four to six hours. After the ten and thirteen drop doses the surface-glow and well-being were more marked—also the drowsiness. The dryness of the throat and huskiness of the voice were more pronounced, and lasted from the forenoon until sundown. A marked sense of fulness in the head after the larger doses is worthy of mention. The appetite was invariably blunted. No dilatation of the pupil was observed at any time.

Each afternoon following the morning of experimentation I felt depressed in spirits. I remained seated for two hours following each dose.

It is deemed pertinent to observe that I am very sensitive to the effect of all potent drugs.

Five drops administered to a phlegmatic adult, of twenty-five years of age, reduced the pulse 12 beats in an hour and caused a slight dryness in throat and voice which passed off rapidly. The character given the pulse was exactly that observed in my own case. The temperature was not taken either in his or my own case.

In conclusion, we would draw attention to one peculiar fact: Neither ten nor thirteen drops of the solution taken into the stomach reduced the pulse much lower than five drops taken in the same manner. The effect of ten drops, instilled into each eye in two days, wore off as rapidly as that of two drops introduced into the eyes of others. As complete an anæsthetic effect seemed to be obtained from a solution of the strength of one-fifth of one per cent. as from a two per cent. solution. Mr. Goodman and Dr. Seward have presented to the medical profession and the world at large a remarkable discovery, whose wide field of usefulness time and experience will limit.

130 Lexington Avenue.

REMOVAL OF LARGE FIBROID WITH UTERUS AND APPENDAGES.

By D. C. BEEBE, M.D.,

SPARTA, WIS.

Mrs. P——, forty years of age, called my attention in April, 1886, to a "bunch" in her right side, which she stated had been coming for seven or eight years. The tumor appeared then to be about the size of a man's fist, and firmly anchored in the right iliac region. The growth seemed smooth, was easily circumscribed, and not sensitive upon manipulation.

It seemed to have then no disturbing influence, except the mental anxiety occasioned by its presence. Menstruation was regular and normal.

I stated to the lady that in my opinion the growth was ovarian, and that, should it continue to develop, removal would be necessary at some future time. Subsequently I saw her at intervals of a few months, and upon examination I could detect a slow growth of the tumor up to the middle of the following winter, when the development was more rapid and its presence more disturbing in many ways.

In September, 1886, I measured the uterus by passing the sound without obstruction, and found no evidence of submucous or intramural fibroid. The uterine cavity was normal so far as I could judge.

Early in the spring of 1887 the growth had increased considerably, was more easily circumscribed, could be easily moved, and had a more elastic feel.

I thought that I could detect fluctuation through the entire growth, and as the patient's general health was now (May) becoming worse, she suffering from pain at epigastrium, loss of appetite, sleeplessness, and general nervous disturbance. I decided to operate, May 31st, and did so, assisted by Drs. Gage and Sarles my partners, and Dr. Smith, of Sparta.

My diagnosis was monocystic ovarian tumor. I omitted stating that Dr. Gage carefully examined the patient with me a few days prior to the operation, made uterine examinations, etc., and agreed with me in diagnosis.

Upon opening abdomen by a median incision extending four inches below the umbilicus, the growth came at once into view, and to the right. It presented externally a peritoneal surface, smooth and shining.

Having the feel of deep fluctuation, not being able to explore much of the growth through the abdominal open-

ing, I thrust into it an ordinary trocar and cannula, receiving upon removal a few drops of blood as a reward.

I then extended the incision one inch above the umbilicus, and drew the tumor far enough into the opening to thoroughly explore it by manipulation. It had no attachments except its principal mooring, which was the uterine neck.

The tumor had, as it were, swallowed up the uterus in the main, the ovaries, and broad ligaments. The ovaries were attached to either side. In size the tumor was about that of an adult head, and in appearance not unlike a gravid womb of six months. At about this time things were becoming interesting; the ovarian cyst of an hour ago was now clearly a sub-peritoneal fibroid that had engaged and swallowed up the uterus and appendages.

These relentless revelations staring the operator squarely in the face suggested to him the momentous question, What is to be done?

To remove the growth entire by amputation of the uterus would give a possible chance. To return the growth to the abdomen (if it were possible) with the bowels and omentum persistently protruding, and close it, would be to execute the death-warrant on the spot.

The former was the mind of all present, and was done with a large chain-écraseur, slowly worked. The neck was firmly secured by two strong double silk ligatures, passed through at right angles, thus ligating it, below the point of amputation, by fourths.

The four ligatures were then brought out at the lower angle of abdominal incision and secured there.

After making the abdominal toilet with care, using the bichloride solution 1 to 2,000, and enforcing extreme cleanliness in all details of the operation, the abdomen was closed and secured by gut and silver-wire ligatures, sterilizing the wound by an envelope of iodoform gauze and borated cotton.

The patient rallied from the operation without much nerve-shock, and for several days she suffered moderate traumatism, her pulse running at times as high as 120, and her temperature once rising as high as $103\frac{1}{2}^{\circ}$.

On the seventh day after the operation all these conditions disappeared, and she had no serious disturbance thereafter.

Drainage was established, by way of the vagina, after the first week, either through the neck or through a small opening made into the Douglas cul-de-sac, in the amputation of the uterine neck with the écraseur.

She was kept in bed seven weeks, with the hope that the ligatures, by making daily tension on them, would become loosened and be removed entire through the abdominal walls. But when, upon examination, August 10th, they seemed obstinately attached, they were cut short and dropped back into the abdomen, where they have peaceably remained to the present writing, September 5, 1887.

The patient has been up and about the house since the date of cutting short the ligatures, and, with the exception of slight œdema of one leg and thigh, she calls herself well.

This case presents to the writer two points of more than usual interest:

1. The difficulty, if not impossibility, of making positive diagnosis in all cases of abdominal tumors from external examination.

2. The removal of the uterus and its appendages a justifiable operation as a last resort.

Traumatic Tetanus is an infectious disease, at least sometimes, possibly always. It is due to the action of a specific infectious virus which exists in the tissues at the seat of infection, in the blood and in the central cerebro-spinal nervous system. Such is the conclusion reached by Dr. E. O. Shakespeare, as published in the *Boston Medical and Surgical Journal.*

A VISIT TO THE NEW BRUNSWICK LAZARETTO.[1]

By HERMAN E. HAYD, M.D., M.R.C.S. Eng.,

BUFFALO, N. Y.

During my holiday season I made a little excursion into the Province of New Brunswick, and while there visited Tracadie—the home of the lepers. This little village is on the northeastern coast of the province, and looks out upon the Gulf of St. Lawrence. A more beautiful and picturesque, as well as healthful, spot could not have been given these afflicted people for their habitation; or a more favored one, with so good a climate—cool and refreshing summers, and cold, dry, bracing winters—to wipe out the perpetuity of this terrible malady. The population is about four thousand—mostly French-Canadians. They are industrious, zealous, and sociable. The houses are small two-story, white, frame buildings, well isolated from one another; and the employment of the people farming, lumbering, and fishing. The farms average from two to forty acres, and their products are principally grass and potatoes.

The Lazaretto, or asylum, is a good two-story frame house, substantially built upon a little elevation of ground, which gives a commanding view of the gulf. It comprises three apartments: one for the Sisters who care for and nurse the lepers; one for the male, and another for the female, patients. It contains at present sixteen lepers: nine male and seven female. There is also a small chapel in connection with the institution.

The disease is quite endemic, and is confined to the two counties of Gloucester and Northumberland, and is seen particularly along the shores of the Baie des Chaleurs, the Gulf of St. Lawrence, and the Miramichi River. Its origin is obscure, and the theories relative to its development conflicting. It is generally believed, however, that the disease was brought into the country. The first case ever heard of was that of a woman named Ursule Landry, who died in 1828, with ulcerating leprosy. Her grandfather came from Normandy, in France, where leprosy existed at that time. Her father and she were born in New Brunswick. Another story is, that she washed some clothing of shipwrecked sailors, who, it is thought, may have had the disease. She was forty-two years of age when the disease was first noticed, and died nine years afterward.

Owing to the very close intimacy of family life, and the sociable habits of the people, and the giving and taking in marriage of nearly related families, the disease spread very rapidly, and soon it reached such alarming proportions that governmental interference became necessary. A system of segregation was adopted in 1844, by the establishment of a hospital. But this compulsory imprisonment and confinement led to so much discord and dissatisfaction that the affected families resorted to every available means to evade the law. They secreted their lepers, taught them to despise the public institution, and assisted them to escape when confined there. But a remedy was soon found. The government lessened its compulsory efforts, and entrusted the care of the lepers to a noble band of Sisters from Montreal, who volunteered their services, and by kindness and sympathy made what was a loathsome prison a desirable hospital. In this work they have been greatly assisted by the clergy, who have gone about from house to house visiting the afflicted families, showing them the dangers of social intercourse with the unclean, arousing and educating public sentiment. By continued patience and vigilance they have succeeded in insulating nearly every leper in the district. When once admitted into the Lazaretto they remain there for life, and have practically no intercourse or communication with the outside world.

They are, of course, segregated as early as possible—in fact, as soon as the disease can be made out. The diffi-

[1] Read before the Buffalo Medical and Surgical Society, September 6, 1887.

culty in connection with early commitments, apart from the pain of separation from family ties and associations, is the taking away from a family of often the only means of support, since a leprous husband or a leprous son can work for years with vigor, and strength, and energy. Therefore the Canadian government, desirous as it is to wipe out this terrible disease, should increase the annual grant to the hospital—which is but a mere pittance of thirty-two hundred dollars—and pension or assist families deprived of support by reason of the fact that their distempered members went early into the public Lazaretto. By such provision the segregation could be more easily accomplished, and the disease in time totally eradicated.

According to the report of Dr. Taché, the governmental inspector, the number of lepers is diminishing, and the disease is slowly but steadily dying out. It is his opinion that the cause of this diminution is segregation; so that, notwithstanding the increase in population, the number of lepers in the province is every year materially less. In 1875 there were thirty-six lepers in New Brunswick, and of this number nineteen were in the hospital and seventeen outside; but to-day, counting those in the Lazaretto, and the few who are not confined there, the total number would not exceed twenty-two.

The general features of the disease are precisely the same as those seen in leprous patients of other leprous districts; and are identical with the leprosy of ancient times, and open the same opportunities for important civic, social, and scientific investigation. Indeed, if you could walk into this institution and study these seventeen patients, manifesting the disease in its various stages of development, you would agree with me, that a more loathsome and horrible disease could not afflict humanity, accompanied by so much mental and physical, as well as moral, suffering, and so certainly fatal. Moreover, you would be surprised to see the patient resignation and the cheerful manner which these poor lepers exhibit—due, I am sure, to the bright and sunny influence of these kind Sisters, and the comforting religion which sustains them, together with the splendid discipline of the institution. It provides hours for religious devotion and meditation, certain hours for recreation, which consists of boating, fishing, etc., and others for general social intercourse. In this way the mind is kept as cheerfully occupied as possible, and shows its salutary influence in a better physical condition of the patients.

I shall not, in this brief paper, enter upon a discussion of those mooted questions in the etiology and pathology of leprosy, but dismiss them by saying that the disease is now generally believed to be slightly contagious and infectious, as well as hereditary. It is due to the presence in the blood and tissues of a definite specific microorganism, or bacillus, called the bacillus lepræ, resembling very much in physical characters and chemical action the bacillus tuberculosis of Koch.

Leprosy is unquestionably contagious; but in all probability an open sore or abrasion is necessary to admit directly some of the discharges from a leprous nodule or sore. A case in point occurred in New Brunswick. A woman died in an advanced stage of leprosy. The body, according to the custom in those days, was encased in a coffin and borne upon the shoulders of four men to the place of burial. The day was very hot and some of the discharges oozed out of the coffin. The friction from the sharp edge of the coffin, combined with the heat and moisture, produced an abrasion on a bearer's shoulder, and through it absorption necessarily took place. In some months the man began to feel ill, and in a short time developed the symptoms of leprosy, and died eleven years afterward. In this case heredity could not be cited as a cause, and, secondly, the man had always enjoyed the very best of health, and was strong and robust.

However, experimental inoculation upon animals has not been successful in producing the disease, as was shown by Professor Heinrich Köbner's efforts upon apes, guinea-pigs, fish, rabbits, etc., as detailed in the Philadelphia *Journal of Medical Science* in October, 1882. One husband of a leprous woman, and one wife of a leprous husband, have had the disease in New Brunswick and died of it, and there were no evidences in any other member of either family. I am also told of a very interesting case, that of a healthy husband having buried three leprous wives, while he himself remained strong and well. These cases go to prove that a certain peculiar vulnerability of tissue, or some peculiar individual susceptibility, is necessary for the successful inoculation, propagation, and development of leprous poison. That any special article of diet, as fish, or any particular occupation or mode of living, or peculiar climatic influence, local or terrestrial, should produce this disease, is without foundation. The counties where the disease is seen are very healthy and the people are not poor. The houses are well built and well isolated from one another, and good food and healthy employment are enjoyed by most of the inhabitants.

However, we must admit that any condition which will lessen the resisting power of the economy, and will interfere with nature's reparative processes, whether it be overwork, poor food, bad hygiene, or what not, might rednce the system so that the fecundation and development of leprous poison would be favored as is any zymotic germ under similar circumstances.

Whether it is infectious in the sense that it can be communicated from patient to patient, as scarlet fever or measles, without contact, is very questionable. That it is an hereditary disease is generally believed, but the same peculiarities and freaks of heredity that are seen in other constitutional blood diseases are noticeable in leprosy, in that it often skips one generation to appear in another; or shows its potentiality in certain members of a family and not in others.

It is mostly seen after puberty, in adolescence and middle life, yet no age is exempt from it; the young child, as well as the septuagenarian, is occasionally attacked by it. The youngest case ever admitted into the New Brunswick Lazaretto was a boy aged eight years. It is also more common in males than in females, and there seems to be a greater resisting power in women, for in them the advance of the disease is much slower. There are now two women in the hospital, who have had the disease forty-eight and thirty-two years, with occasional remissions and exacerbations. Perhaps nine to twelve years is the average duration of the disease. The time of invasion varies, and it is because the period of incubation, and subsequent premonitory development, is so long that we have such difficulty in attributing any special and definite cause for the disease. The symptoms are very variable, and may exist for months, or even years, before any special features of the disease are seen.

Most lepers have complained of general uneasiness, restlessness, irritability of temper, loss of sleep, malaise, aching and shooting pains in bones and body, and repeated attacks of fever for a long time, and various other irregular and indefinite symptoms. After a time the more characteristic features of the disease show themselves—perhaps a crop of blebs, or a macular staining or bronzing of the skin, or the development of irregular nodules or tubercles, accompanied with more or less hyperæsthesia, as well as anæsthesia of the skin. This has given rise to a rather arbitrary classification of leprosy, so that most authors speak of two kinds: *lepra tuberculosa*, and *lepra anæsthetica*, which are in fact one and the same disease, excepting that in the one the skin and the mucous membranes are especially involved, while in the other the nervous system. Yet when one compares two typical cases, as is seen in the New Brunswick hospital, where two brothers are afflicted—the one horribly distorted from tubercular leprosy, so that not a single feature is recognizable, and the other, a handsome young man, somewhat emaciated, with pale yellow skin, but perfect

features—one cannot help but think that the division is a good one. Of course, it is not often that these special characters of the disease are so prominent and so well marked, since usually both forms exist to a greater or less degree in every leper.

These tubercles vary in size from a shot to a small marble, and the skin over them is shining and tense from distention, and they are a little tender to pressure. Oftentimes this infiltration does not take the character of definite isolated nodules, but in its stead are seen great infiltrated masses which produce prominent folds, as on the forehead, where the appearance suggests a lion's head, and hence the name "leontiasis." The nose, and especially the alæ nasi, become thickened and swollen, and stand out in large and irregular masses. The lips undergo a similar change, so that the mouth is horribly distorted and irregular; and, in fact, every feature of the face is so awfully disfigured that the person is beyond recognition. The eyebrows and eyelids are shed early in the disease, but the hair of the head is thick and coarse, and very seldom drops. After a variable period these tubercles break down and ulcerate, and a dirty, thin, ichorous discharge oozes from them. At times the ulcerative action ceases, or is temporarily arrested; but more frequently it goes on and involves deeper structures. It attacks the cartilages and bone, and even dismembers the body by literally amputating the fingers and toes, or even the hands and feet, as is seen in one of the cases in the hospital. The mucous membranes of the nose and mouth, and other orifices of the body, are early attacked, either by a superficial ulceration which may remain quiescent, but more often goes on until deep, ragged, irregular, painful sores result. The soft palate is eaten and perforated in various places, often making communications between oral and nasal cavities. The larynx is early invaded, so that the patient speaks and breathes with difficulty; deglutition is painful or impossible; and finally death kindly puts an end to all suffering by suffocation, asphyxia, or asthenia. Yet, on the whole, one is surprised to see how little pain the average leper suffers, because the same infiltrating and ulcerating process which involves the grosser structures attacks the nerves and terminal nerve-fibrils, rendering the tissues more or less anæsthetic.

That variety called lepra anæsthetica was even more interesting to me, from a scientific standpoint. Although tubercles may be present, and usually are, sooner or later, in the course of the disease, yet they are not a prominent feature of this form. Here the distemper shows its predilection for the nervous system, and through it influences nutrition. The skin assumes a yellow or ashen hue, or, as in the tubercular variety, from pigmentation, a blue or bronzed color, resembling somewhat the discoloration of nitrate-of-silver poisoning. To the touch it is dry, harsh, and rough, and there are often isolated patches covered with fine white scales; and perhaps it is this feature which suggested the simile in biblical literature that the leper was white as snow. There is also present more or less anæsthesia, and analgesia and hyperæsthesia are complained of as well. The muscles begin to atrophy, and I am told that one of the earliest significant features of the disease is the withering of the abductor and adductor muscles of the thumb, so that the thumb appears thinner and more elongated, and the metacarpal space between thumb and index finger sunken. This progressive atrophy continues, and involves the muscles of the hands and feet, as well as the general muscular system of the body, so that in an advanced case the hand is long and claw-shaped, and the body but a living skeleton. As this atrophy advances terrible contractions take place, which result in great distortions and unsightly deformities.

The fingers are crooked and bent upon one another, and the articulations and joints are swollen and immovable. A slight ulceration attacks the skin over the joints, and the ends of the bones begin to soften, and the nails and other structures undergo disintegration, until the whole phalanges are absorbed, or drop off, or even the hands and feet.

Let me here give you the history as well as the gross features of some of the lepers in the Lazaretto.

Peter N——, aged thirty-two. Mother alive and well, aged fifty-two. Father died when seventy-two years of age. Has two sisters and five brothers, the youngest being five and the oldest twenty-five. No other trace of the disease in his family, except grandparent on the mother's side died of it.

He suffered the usual indefinite premonitory symptoms, and was admitted into the Lazaretto twelve years ago. For a number of years he enjoyed good health, and added much to the social enjoyment of the institution in that he is an intelligent and sociable fellow. But during the last years he has failed very much, and now, to say the least, is a most pitiable object. The skin of the body is of a bright, shiny, bronze color, and here and there are seen irregularly shaped, yellowish, pigmented spots, while the palm of the hands is rough and scaly, and of a glistening white color. The skin over the forehead is thrown into a number of distinct folds. The eyebrows and eyelashes have fallen off, the eyelids thickened and everted, and the beard, which was once full, thick, and heavy, is very sparse and thin. The nose is large, broad, and flat, and numerous little blood-vessels—varicose and dilated—are seen over its surface. The septum nasi is absent, and the alæ nasi are thickened and pedunculated, and the anterior nares partially closed from hardened secretions. The mouth is much distorted, the lips are thick and protruding, and the mucous membranes of the cheeks are covered with a grayish ulceration. The tongue is not enlarged, and on it are seen numerous little gray ulcers. The soft palate and pillars of the fauces are partially destroyed, and perforations are seen at its junction with the hard palate, so that communications exist between the nose and mouth. The breathing is stridulous and the voice husky and dysphonic, and deglutition difficult and painful, showing that the deeper laryngeal structures are also involved. The ears are enlarged, and the lobules hang down like two pendent masses. The hands are much distorted, the fingers stiff and crooked, with the phalanges flexed upon the palm, nails absent, and a thin serous discharge exudes from the matrix. Glands of the neck swollen, and freely discharging a thin, stinking, irritating matter. Large ulcers are seen upon the skin, and the tibia itself is painful and tender to the touch, from subacute periostitis. The toes are swollen, and superficial ulcers are seen between them, and over the phalangeal joints the disintegrating and dismembering process has begun.

Joseph B——, aged twenty-six. Tubercular leprosy. Has been in the institution nine years. Condition much like Peter N——'s. Brother entered the same day, but has anæsthetic leprosy. Father and one brother died in hospital, and one sister has been in the institution two years, but is now looked upon as a doubtful case. One aunt and one cousin had it on father's side, and two aunts on mother's side. Mother is now fifty-eight, well and strong, and has been employed in the building as washerwoman for a number of years.

Maurice B——, aged twenty-four, brother of Joseph. Has lepra anæsthetica.

It is very interesting to compare this man's condition, after nine years of the disease, with his brother's. We find him a handsome young man, with dark hair and full beard, heavy eyebrows, and long eyelashes; pale skin, high cheek-bones, rather long nose, broad and high forehead; in fact, quite an intellectual face. There are a few papules on the hands and chest, and a few scattered discolored spots on the body. The hands are much emaciated, long and thin; the interossei muscles very small and atrophied, so that the metacarpal spaces are very deep, and the metacarpal bones stand out in bold relief. The joints are beginning to undergo disintegration. The fingers are bent and distorted toward the palm, and

are always partially flexed, and extreme extension is impossible. There is little or no feeling in the parts—in fact, a pin can be thrust deeply into the tissues and no pain is experienced. The young man's spirits are good, has good appetite and excellent digestion. This is by far the most chronic form of the disease, and may go on for twenty, thirty, or forty years; and with it are seen the most terrible mutilations, where the various members of the body fall off, and hence the term lepra mutilans, a typical example of which is seen in the case of a woman, aged seventy-six, who has had the disease for forty-eight years. She entered the Lazaretto in 1848. Her general health is very good. She has lost all her fingers and toes, and the stumps are clean, smooth, and strong.

The treatment is merely palliative. No case has ever been cured. Some have been discharged and remained at large for variable periods, but sooner or later have returned to the institution. Tonics, good food, good air, and hygiene, as well as sedatives to relieve pain, are indicated; in fact, the various symptoms are treated as occasion calls for.

9 Niagara Street, Buffalo.

MEDICAL CASES IN THE COURTS.

By HENRY A. RILEY, Esq.,

new york.

A recent case in the New York Supreme Court contains many points of interest to physicians, and reference will again be made to the case, but at present we will give the decision of the court on the question of a "violent" death. The action was brought to enforce a policy of accident-insurance which insured against injury by "external, violent, and accidental means."

The insured person died from a malignant pustule, caused by infection from putrid meat in an establishment where he was working. The court says: "Suppose the fact to have been that an insect which had been feeding on the putrid meat afterward alighted on the deceased's face, and even pierced the skin, was this violent? Or, suppose the fact to have been that the deceased himself placed his own hand, infected with this putridity, on his face, was this violent? It may help us to understand the meaning put in this word 'violent' by the defendants, if we examine some of the exceptions made by them. The certificate says that no claim can be made when death has been caused by lifting, over-exertion, sunstroke, or freezing. Now, as these are made exceptions, it is reasonable to understand that without special exception they would have been within the language 'violent means.' Yet sunstroke and freezing do not import physical violence any more than does drowning. We say a man dies a violent death without necessarily implying anything more than that he dies not in the ordinary course of nature and disease.

"If by violent is meant physically violent or forcible, then how great must be the force? Is it not enough, however small it be, if it produces death or bodily injury? A poisoned arrow may make a small wound; but if it produces death, is not that a death by violent means? A rattlesnake-bite may be hardly perceptible. It is hardly possible that this certificate is to be considered as insuring against death from great violence, and not against death from a slight blow. There is an exception in this certificate of 'self-inflicted' injuries, but this must mean intentionally self-inflicted.

"It cannot be a self-inflicted injury when one accidentally stumbles and falls down-stairs, breaking his leg. So that even if this pustule came by the contact of the deceased's own hand, yet it could not justly be called a self-inflicted injury. . . . This is an accident-policy. If the deceased died from disease as distinguished from accident, plaintiff cannot recover. If deceased died from accident as distinguished from disease, he can. Now, undoubtedly, accidents and external injuries often produce death through the disorganization of internal organs, still the accident is the cause.

"On the other hand, it is said that impure water taken into the stomach, or impure air into the lungs, causes fever. But these fevers are diseases having their origin internally. They are not the results of accidents. But in this case there is just what the defendants evidently believed there was not—an external and accidental cause, and not an internal disease manifesting itself externally."

In accordance with this reasoning the court decreed that the company must pay the policy.

In a recent Wisconsin case there were some quite important legal points developed. It appeared that a pregnant woman was arrested, and while in jail gave birth to a child. The arrest seems to have been an illegal one, and suit was brought for damages; and the weak and deficient condition of the child was relied on to enhance the damages. It is said in the record as follows: "Dr. Robinson attended her in prison, and officiated at the birth of her child. He testified that he found her in prison suffering nervous prostration, followed by indigestion and debility; and the drift of his testimony is that, in his opinion, such condition was caused by the nervous shock caused by her arrest and incarceration, and still continues to some extent; and that while she may recover, he does not look for a speedy recovery. He also testified that a pregnant woman in that condition would be liable to give birth to a monstrosity or a deficiency; also, that the plaintiff's child when born was perfect so far as he then knew, but that at the time of the trial, nearly two years later, it was defective in the brain, spinal cord, and nervous system. Dr. Robinson went to Europe in April, 1884, about four months after the birth of the child, and did not return to Wisconsin until May, 1885. It does not appear that he knew or suspected that the child was deficient until after his return. He was permitted to testify that, in his opinion, the cause of the deficiency in the child was the nervous, prostrate condition in which he found the plaintiff in July, 1883. Dr. Robinson was a competent witness to the condition of the plaintiff when he saw her in jail and afterward. He was competent, also, to give his opinion as an expert as to the nature and probable effects of her condition upon herself, and, perhaps, upon her unborn child. But in view of the facts that it is common knowledge that there are numerous causes for physical, mental, or nervous deficiency in children; that healthy women do sometimes give birth to deficient children; that nervous or otherwise unhealthy women often bear healthy children, and that Dr. Robinson detected no defect in the plaintiff's child until it was nearly a year and a half old—we think the authorized limits of expert testimony was greatly exceeded when he was allowed to give his opinion that the deficiency in the plaintiff's child was caused by the nervous prostration of the plaintiff during her pregnancy. The testimony should have been excluded."

In a recent New Jersey life-insurance case, where the insured had allowed the policy to lapse and then had it restored, by making a statement in regard to his health covering the lapsed period, it appeared that the insured, in his statement, said that he had not been "sick, or afflicted with disease." He had had a "cold," as was afterward shown when suit was brought to enforce the policy, but the court held that this fact was not inconsistent with the statement. The words "not afflicted by disease," or "not sick," are not to be construed as importing an absolute freedom from any bodily ailment, but rather of freedom from such ailments as would ordinarily be called disease or sickness. Where a lapsed policy was revived on condition that the insured was in good health, it was held that the phrase was not to be construed as meaning an absolute exemption from any physical ill. The insurance companies are often very technical, as in this case, and it is very satisfactory to notice that the courts and juries decide against them.

Coroners' inquests are of doubtful value, and it is a question whether they aid or retard the punishment of criminals. In two recent cases of very great importance it would seem as if they were a decided hindrance in the way of justice. In the case of the railway disaster at Chatsworth, Ill., where some eighty persons were killed or burned to death, the verdict was one of censure for the section foreman, while the railroad company was allowed to go scot-free. This was rendered in the face of the evident fact that the company allowed an enormously long train to go over a bridge which had not been properly inspected.

The jury was said to have some "friends of the railroad" on it, and the verdict warrants the statement.

In the case of the accident on the Baltimore & Ohio Railroad near the Washington station, the accident was declared by the jury to be "due to the very rapid rate of speed at which trains habitually enter the city, and especially in rounding the curve, which the company must know to be a dangerous point."

The verdict does not go to the extent of saying that the officials were responsible; and yet the accident was a "railroad murder," if there ever was one.

The Bureau of Vital Statistics, of this city, is after the doctors and clergymen with a sharp stick, for their failures to report, promptly, births and marriages. The deaths get recorded with sufficient particularity and promptness, because it is necessary to have a burial permit before the funeral can be finished. People are born and married, however, without it being absolutely necessary to get a permit, and thus it is easy to evade the law. The Health Board are contemplating arresting some of the violators of the regulation, and it is believed that an arrest will induce such persons to put down with great regularity, and report with great promptitude, all facts relating to births or marriages.

The adulteration question is again in the foreground, and deserves to remain there until adequate punishment has impressed offenders with a wholesome respect for the law. The New York statute-book contains a law which says that any person taking to a butter or cream factory any milk diluted with water shall be punished for a misdemeanor. The constitutionality of this law has been attacked, but the Court of Appeals has affirmed its validity, and the conviction of the milk-can fiend has been affirmed.

What is a nuisance? is a question which perennially comes before the courts for adjudication.

In a recent Connecticut case, it was sought to give an answer by showing that a factory which used its machinery so as to jar the windows of an adjoining house and shake the dishes, and which prevented all reading, writing, or conversation, except under great difficulty, was a veritable nuisance. It furthermore appeared that the smoke and cinders fouled clothes hung out to dry, soiled everything in the house, even the food on the table, and affected, injuriously, the health of the inmates.

The defence was, that the neighborhood was one where all kinds of manufacturing was carried on, and that the plaintiff knew this fact when he decided to locate in the neighborhood. The court decided that the vicinity was full of the houses of mechanics and laborers, but was not devoted specially to manufactories, and that any business like the one stated was a nuisance. This decision is good law and sound common-sense.

Live Maggots in the Nasal Cavity.—Dr. F. A. Schmitt reports, in Daniels' *Texas Medical Journal* for August, 1887, the case of a lad, eighteen years of age, who was found comatose, with bloody serum issuing from the nose. The boy having vomited two maggots, an insufflation of calomel was made into the nasal cavities, with the result of bringing away over three hundred worms in the course of nine hours. The maggots had had time to damage the mucous membrane only, and the lad recovered.

A CASE OF RAPID AND ALMOST TOTAL LOSS OF HEARING IN A CHILD, SEVEN YEARS OF AGE; INHERITED SYPHILIS APPARENTLY THE CAUSE; MARKED IMPROVEMENT FOLLOWING THE USE OF THE IODIDE OF POTASSIUM.[1]

By ALBERT H. BUCK, M.D.,

CLINICAL LECTURER UPON DISEASES OF THE EAR, COLLEGE OF PHYSICIANS AND SURGEONS; CONSULTING AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY.

A CHILD, seven years of age, and of somewhat delicate appearance, was brought to me by his parents on January 11, 1887, for the relief of pronounced deafness. The history given by them was, in brief, as follows:

About three weeks previously the child had what seemed to be an attack of croup, which lasted four or five days, and was followed by impaired hearing. The deafness rapidly became so marked that it was almost impossible to communicate with him by speech. Previously to the present attack the child, it was said, had never shown any signs of impaired hearing, although on cross examination the parents admitted that they had sometimes observed a certain degree of inattention on his part, yet not sufficient to make them suspect impairment of the hearing power.

Inflations of the middle ears, according to Politzer's method, were resorted to promptly by the physician in attendance, and were continued, at regular intervals, up to the time when I saw the case—that is, for a period of about two weeks. Noticeable improvement in the hearing, lasting for a few minutes, or for an hour or two, followed these inflations. In the main, however, the hearing power diminished rather than increased, during this period.

At the time when I first saw the child there seemed to be, for all practical purposes, total deafness. From the statements made by the parents, and also from my own observations, I became satisfied that there were brief intervals of time during which the hearing was sufficiently acute for the child to distinguish correctly at least some of the words that were spoken loudly into one or the other ear. A careful inquiry into the previous history revealed nothing that might throw light on the nature of the aural affection. There had been no complaint of pain, no staggering or uncertain gait, no paralysis. On examination both drum-membranes were found to present a somewhat dull and sunken appearance. The dull appearance was of such a nature as to suggest the presence of mucus in the drum-cavities. However, when air was forced into them by aid of the Eustachian catheter, the sound conveyed to my ear, through an auscultation-tube, was that of air entering freely a tympanum of undiminished size, and free from the presence of fluid. This satisfied me that the dulness observed was due not to the presence of mucus, but rather to an œdematous condition of the mucous membrane on the reverse side of the membrana tympani. The hearing seemed to be impaired to an equal degree in both ears. There were ample evidences of nasal and naso-pharyngeal catarrh.

In the matter of a diagnosis I was obliged to confess that both the nature and the precise seat of the disease were unknown to me. The rapidity with which the hearing had disappeared, and the apparent absence of physical changes in the middle ears adequate to explain the deafness, favored the hypothesis of lesions involving the labyrinth; while, on the other hand, the development of the deafness in connection with a croupy attack, the existence of decided catarrhal manifestations in and about the ear, and the temporary improvement brought about by inflations of the drum-cavities, favored rather the idea that the affection was, after all, simply a subacute catarrhal inflammation of the middle ears with an unusual degree of secondary labyrinthine congestion. At that

[1] Paper presented to the American Otological Society at its annual meeting in New London, July 21, 1887.

time there were no visible lesions in the external auditory canals; or, if they were present, they were so insignificant as to escape my notice.

Under these circumstances I gave a guarded prognosis, and recommended a plan of treatment based on the supposition that the disease was simply catarrhal in its nature.

On January 26th I noticed, for the first time, the existence of a circumscribed area of redness (localized periosteitis) on the posterior and upper wall of the right external auditory canal, in close proximity to the membrana tympani. The redness of the skin did not extend perceptibly beyond the periphery of the latter membrane. An examination of the left ear showed that almost precisely the same condition of the parts existed in that ear; the only difference being that the redness was somewhat less pronounced on one side than on the other. In the absence of pain, of fever, and of any other sign of an ordinary inflammation, and from the fact that the family history was not entirely free from a tubercular taint, I drew the inference that the case in hand was one of tubercular osteitis involving the bony floor of the antrum, and extending inward and forward as far as to the fenestra ovalis and probably into the labyrinth itself. With this new light on the case I suggested to the attending physician that in addition to the inflations and tri-weekly applications of silver nitrate to the vault of the pharynx, cod-liver oil and Huxham's tincture of cinchona should be administered internally, and a modified Wilde's incision[1] made behind the right ear. It was hoped that, by the aid of the decided counter-irritation which would be established by this last measure, the inflammation of the bone might be made to subside.

February 10th.—The incision was made as suggested, but the localized periosteitis still persists, and, so far as the eye can discover, it has not materially diminished in degree. The external wound has healed. There is a slight improvement in the hearing, according to the statement of the parents, but it is not recognizable by the physician.

February 15th.—Incision repeated, on the same side, and wound stuffed with coarse oakum, with a view to exciting more decided counter-irritation than before.

February 21st.—Very little inflammatory reaction has followed both this and the first incision, and no recognizable benefit has resulted from the procedure.

By the merest accident I learned to-day, from a person who had been acquainted with the child's parents in earlier years, that both of them had had syphilis before the birth of the child. I made careful inquiries in regard to the ailments and general condition of health of the patient prior to the attack of "croup," but failed to obtain any satisfactory information. From the attending physician, however, I learned that the patient was a pale, delicate babe. He had no serious illness during the first year. When a little over a year old he began to have attacks of vomiting, and at varying intervals they would recur. They began by his emptying his stomach, and then he would retch and throw up whatever he took, for three days. They got to expect a three days' siege whenever an attack began. There was no system or regularity about their return. There were no head-symptoms nor anything simulating a convulsion. The mother had had one miscarriage and had lost two or three children at an early age. An examination of the child's incisor teeth (not yet the permanent ones) shows no evidences of the characteristic defects described by Hutchinson.

Again the treatment was changed. All attempts at counter-irritation were abandoned, no further applications of silver nitrate were made to the vault of the pharynx—which, in fact, seemed then to be in so nearly a normal condition as not to require any further active interference—and the child was put under a regular course of potassic iodide, in slowly increasing doses. It was also suggested that mercurial inunctions should be added, later, to the internal administration of the iodide. My impression is that this part of the treatment was not adopted.

On March 27th the attending physician reported that the child was improving, both in his general health and in his hearing power. The iodide of potassium had been given, at first, in five-grain doses, three times a day, but the dose had been gradually increased, and at that date it had reached seventeen grains, three times a day. The cod-liver oil and compound tincture of cinchona had also been continued. "There is no change," his physician writes, "in the appearance of the external auditory canal that I can discover. The remedy has not yet shown its effect on the skin or in any other way; but the child hears better. Of this I am positive."

I quote again from a letter dated June 11th: "He has taken the iodide regularly since I wrote you last, and is improving quite steadily in respect to his hearing. He took at one time thirty-eight grains, three times a day, but it caused some coryza and he has taken less since. I have not seen him, until to-day, for nearly six weeks. Meantime he has developed a trouble with the left eye, the nature of which I do not understand [keratitis parenchymatosa?]. The chief symptoms are photophobia and watering of the eye. His parents have during this time taken the responsibility of reducing his iodide to seven and a half grains, three times a day. I have directed them to increase it again. The child's general health is good. He is growing, but not increasing in weight."

In answer to my request for more detailed information in regard to the condition of the hearing, the doctor writes, under date of June 18th: "He hears equally well, as nearly as I can ascertain, with both ears. He would not hear an *ordinary* tone to know what was said. He would hear a tone *slightly* elevated, if the words were spoken slowly and distinctly. His parents think he hears ordinary conversation at times." Again, on July 12th, he writes "that one of the child's knees has been in a swollen condition since ten days ago. There has been no pain, however, nor does it hurt him to use it."

Remarks.—It seems to me that there can be very little doubt in regard to the syphilitic nature of the lesions which damaged this child's hearing so seriously. The miscarriage experienced by the mother, the loss of two or three of her children in infancy, the selection of the bony parts of the ear by the disease for its first centre of activity, the subsequent development of inflammation of the eye, and then of some sluggish disease of the knee, and, finally, the markedly beneficial effects of potassic iodide administered internally—all these facts, I believe, favor strongly the idea that the case was one of tardily developed inherited syphilis.

A number of similar cases have been reported by Knapp, of New York (vol. ix. of the "Archives of Otology," where the earlier literature of the subject may be found); by Kipp, of Newark, N. J. (vol. ii. of the "Transactions of the American Otological Society"); and by others. The chief point of interest in the present case lies in the fact that a circumscribed periosteitis was demonstrable, for a comparatively long period, at symmetrically placed spots in both external auditory canals. These spots corresponded to the bony floors of the mastoid antra. In all other material respects the case differed but little from those hitherto reported.

The discovery of a limited periosteitis (and undoubtedly also osteitis) at the very spot where tubercular disease of the ear is apt to start, suggests the question whether, in cases of deafness due to tardily developed inherited syphilis, this spot, or one very close at hand, be not also a favorite seat of syphilitic lesions.

In view of this possibility, I would suggest that particular attention be directed, in cases such as we are con-

[1] Incision of the mastoid integuments, followed by stuffing of the wound with lint or other irritating material.

sidering, to that part of the external auditory canal which lies immediately next to the posterior upper limit of the membrana tympani. I am confident that even a careful observer may, in an unguarded moment, very easily overlook a certain amount of redness of the skin at this point, because it is not unusual to find very nearly the same state of things in cases of simple subacute catarrhal inflammation of the middle ear. The distinction between the two, however, may be stated thus: The redness of syphilitic origin is likely to be most marked at a spot lying directly upon bone-substance, while that due to simple catarrh is most marked along the manubrium mallei and at the periphery of the membrane, and then fades away rapidly from the periphery outward.

While, in the present instance, the administration of the potassic iodide alone, without mercury, appears to have been reasonably successful,[1] I find that a recent writer on this subject[2] lays considerable stress on the necessity of not trusting to this drug alone, but of employing at the same time, in conjunction with it, mercurial inunctions.

Progress of Medical Science.

Some of the Rarer Forms of Rectal Fistulæ.—At a recent meeting of the West London Medico-Chirurgical Society (*British Medical Journal*), Mr. Edwards read a paper in which he discussed the question of dealing with the sinus, extending upward by the side of the bowel, from the internal opening of a complete fistula. The treatment should depend upon the position of the sinus to the muscular coat of the bowel; if submucous it should be laid open, but if submuscular it was better to leave it, thus avoiding the risk of incontinence due to division of the fibres of the internal sphincter. A cure might be looked for after the frequent injection of the sinus with tincture of iodine. Fistulæ having their external orifices situate behind a plane passing transversely through the centre of the anus, usually had their internal aperture in the middle line dorsally, while those with their external orifice in front of this plane generally terminated in an internal opening immediately opposite. He defined horse-shoe fistulæ as having one or more external orifices on either side of the anus, with an internal one in the middle line behind. Surgeons of the present day, when operating upon such fistulæ, either slit up the sinus on both sides of the gut, thus dividing the sphincter in two places, or contented themselves with the division of one sinus, hoping that the other might heal of itself, with or without the insertion of a drainage-tube. Mr. Goodsall recommended complete division of the sphincter in the middle line, dorsally, laying open the abscess cavity and internal opening, and the subsequent slitting up of each lateral sinus from the external orifice to the central dorsal incision. By this means the whole of the fistulous track would be laid open, and the sphincter would only suffer one division, and this in the most favorable manner, namely, at right angles to its fibres, thus avoiding all risk of subsequent incontinence. Cases were related, one of fistula completely encircling the bowel, and the other of fistula originating in the pelvi-rectal space, that is, between the bowel and levator ani muscle.

Poisoning by Nutmeg.—The following instances of this accident are reported in the *British Medical Journal* by various correspondents. A middle-aged woman took one nutmeg, scraped and mixed with hot water, as a remedy for arrested menstruation. Two hours after taking it she was seized with extreme thirst, giddiness, and prostration; but to her the most painful effect was, in spite of the prostration, an intolerable restlessness, causing her to tramp up and down the room almost incessantly, holding on to the various articles of furniture for support; there was also "tightness of the chest," obliging her to loosen her dress. The symptoms continued (in spite of an emetic, strong coffee, and sal volatile) more or less during the whole of the evening and night, and then passed off completely. To judge by the paucity of the information in the text-books with regard to poisoning by nutmegs, it must be a very rare accident, and as nutmeg is so constantly taken as a flavoring for puddings, etc., even by very young children, it leads to the belief that, as in the case of the poisonous fungi, the toxic properties must be liable to great variations, caused by peculiar conditions of soil or season. A young lady one evening ate a whole nutmeg, being fond of it; this was about 7 P.M. Shortly afterward, feeling sleepy, which she ascribed to having been up the greater part of the previous night at a ball, she went to bed, and slept very heavily till late next morning, when she was with some trouble aroused. She got up and dressed, but had no appetite for breakfast, still felt very drowsy, and vomited slightly several times. When seen, about 10.30 A.M., vomiting had stopped, her face was pale, and she was unable to raise her eyelids; she did not complain of any giddiness, only feeling very drowsy and great disinclination for exertion. The treatment adopted, and under which the symptoms quickly passed off, was the use of strong coffee, cold douching of the head and face, enforced exercise in the open air, and a mixture containing ammonia. A physician was called one evening, about ten o'clock, to see Mrs. E. M——. He found her complaining of giddiness, faintness, and disturbed vision. The pulse was feeble, the skin cold and clammy, pupils dilated, no pain anywhere. He was told that she had taken the whole of a medium-sized nutmeg, scraped up and steeped in gin, as an emmenagogue. The treatment adopted was to administer an emetic, which had the effect of bringing away a large quantity of the nutmeg. He then gave her brandy, ordered her to be wrapped in blankets, and hot-water bottles applied to her feet. He also gave her a stimulating mixture and an aperient. Next morning the patient was nearly well, only complaining of a feeling of lassitude.

Cocaine in Tonsillitis.—Boeckel has recommended the application of strong solutions of cocaine to inflamed tonsils. He used a ten per cent. solution, applying it at intervals of fifteen minutes. The pain disappeared like magic after the third application, and the anæsthesia lasted an hour. The drug, however, caused a temporary paralysis of the muscles of the soft palate, so that when he attempted to drink the liquid immediately escaped from the nose. After five hours the abscess ruptured spontaneously, two days earlier than in his previous experience. He warmly recommends the application of a solution (five to ten per cent.) of cocaine at the beginning of an attack of tonsillitis.—*Rev. mens. de Laryngologie.*

Is Alcohol Incompatible with Pepsin?—This is one of the many questions of therapeutics that has most divided chemists and practitioners, and has caused the greatest divergence of opinion. The controversy is of perhaps fifteen years' standing, if not more, for some thirteen or fourteen years ago it was already discussed by Mr. Phillipp, before the Alumni Association of the New York College of Pharmacy. The Paris Société de Thérapeutique, an association including both physicians and pharmacists, recently gave the question another overhauling, the conclusion of which may fairly be said to be that alcohol is and is not incompatible with pepsin, according to circumstances. Dr. Bardet, Dr. Dujardin-Beaumetz's *chef de laboratoire* at the Cochin Hospital, led the discussion with an elaborate paper, well supported by experiments, and gave it as his opinion that up to

[1] While this article was in the hands of the printers, I learned from the attending physician that the boy now (September 13, 1887) seemed to hear as well as ever. —A. H. B.

[2] A. Wolff: Ueber Syphilis hereditaria tarda. Volkmann's Sammlung Klinischer Vorträge, No. 273.

twenty per cent. of alcohol is a proportion that pepsin solutions can stand with perfect impunity. Above twenty-five and up to seventy per cent., the loss of digestive power is in exact proportion with the excess of alcohol introduced. Above seventy per cent. the ferment is killed, just as albumen is suddenly coagulated at a certain temperature. This property explains the inertness observed by M. Catillon in specimens of pepsin precipitated by alcohol from glycerine or watery solutions. As to the loss occurring when wine is used as a solvent, it should be attributed to the tannin, not to the alcohol of the menstruum. M. Pierre Vigier partly agreed with Dr. Bardet, his own experiments having convinced him that eighteen or twenty per cent. of alcohol does not seriously impair the digestive ferment, although its power be somewhat injured. For this reason the revisers of the French Codex were right in admitting to the official list, notwithstanding Dr. Vulpian's opposition, wine and elixir of pepsin, two excellent preparations. But Dr. Bardet maintained his position; his experiments are conclusive, and prove that a proportion of alcohol not exceeding twenty per cent. has no untoward effect on pepsin, and it is only when twenty-five per cent. is reached that the ferment begins to be injured; the same result may be accidentally produced when alcohol is too rapidly added to solutions of pepsin, because then a portion of the digestive ferment may come into contact with a destructive proportion of alcohol.—*Therapeutic Gazette*, August 15, 1887.

Fragility of the Umbilical Cord.—At the Société de Médecine Légale, M. Descoust combated the opinion of M. Budin as to the fragility of the umbilical cord. He often tried to break it, in post-mortem experiments, in holding the child up by it, but it slipped through the fingers easily and was broken with difficulty. M. Budin replied, giving credit to his honorable antagonist for his views, as, if it were proved that the dead weight of the child was insufficient to break the cord, then it should be supposed that the cord was dragged purposely or even cut. But there is abundant evidence as to the spontaneous rupture occurring when the woman was delivered in the standing position or in the water-closet. He cited a recent case. A servant living in a faubourg of Paris, came to the Maternité in the month of December last. She said that she was *enceinte* about eight months, and that a few hours before she felt a lot of water running from her. Her mistress advised her to go immediately to the hospital. Before she left she had a desire to go into a water-closet, but remarked nothing particular. On examination it was found that she was already delivered, at which she seemed much astonished. The placenta had also come away and was found at the door of the hospital, with the cord torn across. The child was subsequently found dead in a water-closet. M. Vibert said that he fully believed in rupture of the umbilical cord when the woman was delivered standing, but in the case cited by his learned friend he could not look on it in the same light, and before a court he would deny its possibility. However, he was inclined to take into consideration the expulsive force, which in some cases is very great, and might produce a spontaneous rupture.—*Medical Press*, August 17, 1887.

Siegesbeckia Orientalis for Ringworm.—Dr. J. Hutchison, of Glasgow, writes: *Siegesbeckia orientalis* is a shrub, the green parts of which have quite a reputation in the Mauritius. For internal administration a syrup is prepared by pounding the green plant, adding sugar, and straining. This syrup is considered a powerful alterative, and is given in syphilis, gout, scurvy, scrofula, etc. For external use a poultice is made of the bruised leaves, and applied to gangrenous and sloughing sores with marked healing effect. The plant has been introduced into England, and placed within the reach of medical men here. I have used it in 15 cases of ringworm; of these 8 were cases of tinea circinata, 4 of tinea sycosis, 2 of tinea tonsurans, and 1 of tinea versicolor. The site of the 8 cases of tinea circinata was in 6 of them upon the neck, and in 2 upon the calf of the leg. None of the patients called upon me till the disease was well developed, when the red, raised, circular, bounding edge, and the pale central area, with its branny desquamation, left little doubt of the diagnosis. The four patients who were afflicted with tinea sycosis all blamed a "foul shave" for their ailment. In all of them the disease was upon the chin, and presented the characteristic fig-like appearance. The two cases of tinea tonsurans showed the roundness of the diseased patches, the scaly eruption, and the brittleness of the hairs peculiar to that form of the trouble. The one case of tinea versicolor was also typical. My prescription in all of them was the same, namely, equal parts of tincture of siegesbeckia and glycerine, and this I ordered to be well rubbed into the affected area night and morning. The drug appears to act both as a stimulant and a parasiticide, and the method of cure was for the diseased patch to become broken up into a number of smaller patches, with sound skin intervening. These smaller patches became again broken up till they disappeared altogether, and in their place was left a red blush, as if the part had been struck a smart tap with a cane. The redness, however, only remained for a day or two. The two cases of tinea tonsurans were the most stubborn to give way, but even in their cases more frequent applications, and continuing the treatment over a longer period, brought about the result desired, and that, too, without resorting to epilation.—*British Medical Journal.*

Urobiline.—At the Société Médicale des Hôpitaux M. Hayem recently gave an account of his researches on *urobiline*, one of the pigments of the blood met with in serum, urine, and bile. Serum does not contain a sufficient amount of urobiline to be easily detected, but with the addition of a few drops of a solution of iodine it readily appears. With the spectrum it gives a black line between the green and the blue. It seems to be a product of the bilirubine and biliverdine, and is formed in the intestine. It can be found in acute gout, pneumonia, pleurisy, rheumatism, etc. Among the chronic diseases in which it is constantly met with are heart affections, liver disease, tuberculosis, etc.—*Medical Press*, August 17, 1887.

Are Starch-containing Foods Dangerous to Young Infants?—At a recent meeting of the Clinical Society of London, Mr. Parker, Surgeon to the East London Hospital for Children, read a paper on the alleged dangers of starch-containing foods during the period of infancy, in which he took a different view of the subject from that now entertained by the best authorities on pædiatrics. (*Gaillard's Medical Journal*, September, 1887.) After many years' work in a children's hospital, he has arrived at the conclusion that the dangers of this kind of food are very greatly exaggerated, and he does not hesitate to say that he has never himself met with cases in which he could distinctly and directly trace disorder to starchy foods. His object in making these statements is not to advocate artificial feeding in preference to nursing, but to draw attention to what he believes to be the real and proximate causes of the immense mortality which obtains among young children, especially among the children of the poorer classes—namely, congenital debility. "It cannot be gainsaid," he says, "that very many artificially-fed children are puny and weakly, and it has come to be generally accepted that the children are puny and weakly because they are so fed. On the other hand, an analysis of any one hundred wasted and weakly children will show that a considerable number of them are breast-fed; and further, that of those which are being artificially fed many were puny and weakly when artificial food was commenced, and that artificial food was either added to the nursing, or sub-

stituted for it, because the children were not thriving. What inferences, then, are to be drawn from these facts? First, and chiefly, that many children are congenitally deficient in the vitality and digestive power which are absolutely essential to their healthy development. Such children will be weak and puny on any diet. Such children as these, moreover, are just the kind of children we should expect to be born of women (of parents) themselves weakly, either congenitally or from acquired causes, such as irregular modes of living, drink, poverty —leading as it does to privation of every kind; food, fresh air, light, rest, etc. Can women exposed to such conditions as these be expected to give birth to strong, healthy children, or even to produce good milk in sufficient quantity to nourish their children properly?" Toward deciding the issue raised, he gives an analysis of a hundred histories of artificially fed children, under twelve months of age, taken from among his unselected patients attending the East London Hospital for Children, which shows, he thinks, that in a very large percentage of cases the lowered health-status of the mothers is obviously the reason why artificial feeding of their children has to be adopted. "It does not need any long experience," he goes on to say, "to enable one to predicate that if the mothers are weakly their offspring likewise will be weakly. It follows, therefore, that the reason why so many children are fed on artificial food is that they do not thrive on the breast-milk of their mothers, or that they do not thrive on that alone. Thus, in estimating the causes and treatment of marasmus and other kindred diseases in infancy, it seems to me that too little stress is laid on the congenital debilities under which vast numbers of children labor, and too much stress is laid on artificial feeding, especially on the injurious effects of starch-containing food." He does not question the immense value of good maternal nursing, nor underrate the dangers and disadvantages of artificial feeding. He states that he simply questions the truth of the belief that starch-foods are actively injurious, and for the following among other reasons: "That many and many a child is now alive and well to testify against such a doctrine; that in years gone by, before malted foods came into vogue, hundreds of children throve upon milk thickened with a little of one or other of the common starch-containing cereals; that there are no experimental investigations to warrant such an assertion; that, as is well known, animals, when fed on starch, do not get rickets and the diseases usually attributed to starch-feeding—they die of inanition; that the starch taken in with the food passes out with the fæces unaltered. If it could be shown that the starch was broken up into other and deleterious compounds, there would be something to go upon; but, as a matter of fact, the starch passes out of the body unchanged." In this connection it may be of interest to refer to the examination of the fæces of twenty-four starch-fed infants, made by Dr. N. A. Randolph, two years ago, in the physiological laboratory of the University of Pennsylvania. Although the number of cases was small, the results are certainly unexpected and remarkable, since these showed that the presence of starch was exceptional, and apparently in no degree dependent upon the age of the child. The stools of eighteen out of the twenty-four children contained either no starch, or but a trace, *i.e.*, no more than is frequent in the evacuations of a healthy adult upon a mixed diet. Six of the specimens examined were from children of three months or less, the youngest being but forty-five days of age. In many cases the broken and empty cellulose envelopes of the starch-granules were clearly discernible. From these experiments, then, it is concluded that many infants of under three months can digest starchy foods, and that the individual variations, in this regard, are so numerous that no broad and general statement can be made as to the period at which infants begin to digest starches. It would seem, therefore, if these experiments are to be relied upon, that Mr. Parker and most other writers are mistaken in supposing that starch is not digested by young infants, but passes out of the body unchanged, except it may be in comparatively rare instances. Until the present time, however, it has been an undoubted fact, as he asserts, that the belief in the dangers of starch-food during infancy is widespread and generally accepted in the profession. Hence he thinks that there should now be a reconsideration of the starch-dogma, and it certainly does seem desirable that a full and impartial scientific investigation of this important subject should be made. But whether his views as to the innocuousness of starch should be confirmed or not, his paper is likely to prove of service in attracting attention to the fact that considerable harm has no doubt resulted from the almost exclusive attention which by many has latterly been bestowed on this element in infantile dyspepsia, and to the importance of more generally taking into consideration the congenital condition which may be largely responsible for the existing athrepsia.

Rectal and Dermal Alimentation of "Wasting" Infants.—In the course of an address on the dyspepsia of infants, delivered by Dr. Sansom (*The Medical Press*, July 27, 1887), the following practical suggestions are made: "Nourishment may be conveyed to the wasting infant by other channels than that leading to the stomach. Supplementary alimentation, until such time as the normal processes reassert themselves, is a most important therapeutic method. Something may be done by inunction. Cod-liver oil may be rubbed into the skin, and there seems to be very good evidence that this measure is productive of benefit. Still more valuable, however, is supplementary alimentation of the rectum. Food administered by the rectum should be predigested or converted into peptone. The simplest way of making a meat peptone enema for an infant or young child is, I think, the following: Shred raw beef or mutton in bulk about two tablespoonsful, add an equal bulk of water, and let stand for an hour; then add gradually four tablespoonsful of milk, heated to boiling. When all is well mixed the temperature of the mixture will be about 140° F., then add a teaspoonful of Savory & Moore's or Benger's liquor pancreaticus, and a pinch of bicarbonate of soda. Let the whole remain for six hours, and then heat to boiling. Strain through muslin and preserve the liquid, which will suffice for several enemas. A nutrient enema must be administered to an infant or young child very gently and gradually, but it is retained much better than *prima facie* considerations would lead one to expect. Not more than two ounces should be administered at a time. A ball syringe holding this quantity may be used, but the simplest and best method is to employ a small funnel or curved tube (such as is used for the application of leeches) to which a large, soft, flexible male catheter is attached. The catheter being gently introduced some distance into the rectum, the fluid to be injected is poured into the funnel; the latter is then elevated so that the fluid enters the rectum chiefly by the force of gravity. The fingers are then used to express into the rectum the fluid remaining in the catheter. Then the catheter should be slowly withdrawn. Still simpler than this peptone enema is the enema of cod-liver oil and milk, which I have used in many cases with very good results. This consists merely of equal parts of cod-liver oil and warm milk shaken together in a bottle till well mingled; it is, of course, administered in the manner previously described. It may be asked whether diarrhœa is a bar to the use of nutritive enemata, and the answer is, certainly not in all cases. In some there is a sedative effect upon the rectal mucous membrane and the irritability of the bowels manifestly subsides; but there are cases in which it is evident that the enemas cannot be tolerated."

In the Treatment of Cirrhosis of the Liver, M. Lanceraux thinks that the three great measures are hydrotherapy, iodide of potassium, and a milk diet.

RECENT INVESTIGATIONS CONCERNING IODOFORM.

THE attack upon iodoform by Heyn and Rovsing has been beneficial, in stirring into activity a number of persons eager to learn the truth regarding the utility or otherwise of this substance in surgery and medicine.

Our readers will, we are sure, be interested in a brief review of the various contributions made of late, chiefly by German observers.

König (*Therapeut. Monatsch.*, 1887, April; *Centralbl. f. Chirurg.*, No. 37) contributes the results of several years' experience with iodoform in the treatment of wounds, and claims for it a positive value. Iodoform has feeble germicidal properties—so little, indeed, that it needs to be carefully purified itself. It is no specific against tuberculosis, in that it does not prevent the development of tubercle-bacillus. It acts only upon the healthy wounds freed from tuberculosis, preventing development of bacteria and promoting primary union. König does not think that it is wise to abandon iodoform, for it has, he believes, a real value; but he thinks that other substances may accomplish the same results.

Professor C. Binz, five years ago, showed in connection with König the peculiar drying action of iodoform. He now publishes the result of some experiments with iodoform upon the inflamed mesenteries of frogs (*Therapeut. Monatschrift.*, 1887, May), from which he concludes that it prevents the emigration of white blood-cells.

Dr. G. De Ruyter has experimented partly in the laboratory of the Hygienic Institute at Berlin, partly in the surgical clinic of the University (*Archiv f. klin. Chirurg.*, Bd. xxxv., Hft. 1). He found that iodoform powder outside the animal body was practically powerless against pathogenic micro-organisms. Strewn on bacteria-cultures, it at most only delayed the growth, and when *spread over infected wounds, the animals died just* as quickly as those in which the wounds were not so treated.

On the other hand, De Ruyter finds that in the animal body the iodoform is decomposed, and in part prevents the development of bacteria, in part makes them and their products harmless. Solutions of iodoform which allow of this decomposition are most valuable, and the author particularly praises a mixture of iodoform one part, ether two parts, and alcohol eight parts. Cultures and infected wounds treated with this solution were made sterile and innocuous.

Dr. H. Sattler, of Prague, has written upon the antiseptic value of iodoform and iodol (*Fortschrift der Med.*, 1887, Bd. v.), more particularly with reference to its use in eye-surgery. Dr. Sattler takes it for granted that iodoform does have antiseptic power. The experience of surgeons for years forbids one to doubt it. The question is, how and in what conditions does it act in this way? In answering this the author does not seem to have evolved anything new. He claims to have proven that iodoform does inhibit the vital activity and harmfulness of micro-organisms, by virtue of decompositions which set free iodine or some of its compounds; also, that the antiseptic action is confined to the parts close to the iodoform molecule. On account of its certainty, continuous action, and non-irritability, Sattler thinks that in many points iodoform is without a rival. Iodol has nearly the same properties, but is more irritating.

Baumgarten (*Berlin. klin. Woch.*, 1887, No. 2; *Centralbl. f. Chirurg.*, No. 37) denies the antiparasitic action of iodoform, upon the ground of certain experiments made by himself and Kunze. He injected masses of tuberculous matter rubbed up with iodoform into rabbits and guinea-pigs. They died of tuberculosis. Tuberculous matter treated with sublimate did not produce tuberculosis. Similar experiments were made with septicæmic anthrax- and pus-organisms, and all were unfavorable to iodoform. Death was delayed, but never averted.

Somewhat similar experiments to those of Baumgarten were made by Th. Rovsing, of Copenhagen (*Fortsch. der Med.*, Bd. v.), and with similar results. Rovsing injected tubercle that had been treated with iodoform into the anterior chamber of the eye of rabbits; tubercular nodules promptly developed.

Directly contrary results to the foregoing are furnished by P. Bruns and Nauwerck (*Mittheilungen aus der chirurg. Klinik zu Tübingen*, 1887, Bd. iii.). They extirpated parts of the walls of tuberculous abscesses, and examined them microscopically. After treating the abscesses with iodoform until they were much smaller, the walls were again examined and the tuberculous tissue found gone or nearly so. Eight cases were thus treated, and the conclusion is reached that iodoform has specific anti-tuberculous properties.

Dr. A. Lübbert, of Dresden, in an article upon the relations of iodoform to the *Staphylococcus pyogenes aureus* (*Fortschr. der Med.*, Bd. v., p. 330), gives the results of forty-three experiments upon animals, in which he tested the results of iodoform applications on infected wounds and in preventing infection. The results were all against iodoform.

A review of the foregoing shows that iodoform is not a powerful antiseptic, or very destructive to the life of micro-organisms. Bacteriological experiments, as a rule, are quite against it, but practical surgical experience continues to favor it. The conclusions of König appear to represent current surgical opinion most fairly.

FEES FOR VENEREAL DISEASE.

OUR esteemed contemporary, *The Medical Press and Circular*, finds fault with our views upon the subject of fees for venereal disease. We fancy, however, that there is no serious difference of opinion regarding the

matter. It would be monstrous to assume that the physician had any right to charge higher fees because his patient's disease followed vicious indulgence, and we have not assumed such a position. The physician, however, does have a right to charge more for treating disorders that are uncleanly and disgusting, not to say personally dangerous. It is for this reason that he may be justified in asking a higher fee for treating a catarrh of the urethra than for a catarrh of the pharynx. As for his mental attitude in the matter, each man has a right to feel sympathetic or otherwise, as his temperament or conscience dictates. Our esteemed contemporary may feel assured that there is no emergency in life in which it will not receive from us the assurances of our warmest consideration.

TRAINED NURSES IN SMALL COMMUNITIES.

PROBABLY there is no one who is not an advocate of the trained-nurse system. Even those who decry it do so on insufficient grounds. The general testimony is in its favor. A few nurses may be somewhat presumptuous; the majority are obedient even to a fault. Now and then a physician may meet a nurse who, without any special training, has become, by long experience, admirably qualified for her duties. There are in every calling a few who seem to have been born with a "knack" for it. To nearly everyone, however, ability comes only after a systematic striving therefor. All friends of trained nurses must admit, however, that this new calling is only in its infancy, that its sphere is restricted, and its benefits attainable by only a few. The law of supply and demand is so working at present that large wages can be secured by all training-school graduates, and only the very-well-to-do can employ them. As has been said, nurses are not now obliged to begin at the bottom of the ladder, as is the case with other professional workers. They begin their ascent from a landing already well up toward the top.

It is not our aim to cheapen the services of these new helpers. The monetary value of their labors will in due time feel the effects of competition, as happens in every new occupation. But we plead for the establishment of training-schools in small communities, where people of moderate means make up the bulk of the population. In large cities there are ample hospital accommodations for those who must have a trained nurse and cannot pay for her. In smaller places there is often no hospital, and at present there is a large class moderately able to pay, but as yet wholly unprovided with proper nursing.

An interesting paper was read on this topic, at the last meeting of the Massachusetts State Medical Society, by Dr. Worcester, of Waltham. In the latter city a small school has been established, entirely apart from any hospital, except as the latter has on a small scale grown out of the former. A body of ladies and gentlemen became patrons and patronesses, and made an annual guarantee. The services of a few young women were secured, and the physicians of the place agreed to give instruction. A lecture was delivered to the class, in some convenient place, five times a week. A two years' course was established, and small monthly wages paid to the members of the class. If any of the physicians had a patient desiring a nurse, a pupil was detailed for the case. For a first-year pupil the charge was, we believe, seven dollars a week, and for a second-year ten dollars.

During the first year the guarantors were called upon for a small payment. Since then the affair has become a self-supporting one. Out of the work has grown a small hospital, in a properly selected tenement, which makes a headquarters for the school. Thus, in a quiet way, has grown up, without great expense and without any undue effort on the part of any single person, an institution at once an honor and a blessing to the community in which it is situated. It is modelled after similar city institutions, and, like them, gives a diploma to its graduates.

The establishment of a cottage-hospital and small training-school in provincial communities introduces a social factor of the utmost value. About it many isolated charitable projects can cluster with mutual advantage. It becomes a so-called charity organization society, of which there is often as much need in small places as in large. In undertaking its foundation, local physicians can greatly increase their influence in the community. They can secure better care for their patients, and thus relieve themselves of a great deal of anxiety.

A NEW SPECIALTY WANTED.

DESPITE a general feeling that specialism in medicine is a little overdone, we are impelled to urge upon the attention of our readers the need of one more subdivision in the medical art. We should call the followers of it by the name of "gastrologists," and their peculiar line of research should be the stomach, with, incidentally, the intestines, liver, and spleen. Whenever an organ of importance has been made accessible to methods of exact research, a specialty is bound to develop in connection with it. The stomach has of late years become one of those organs. In former years its disorders were diagnosticated almost entirely from subjective symptoms. The physician heard the patient's story, looked at his tongue, and that was the end of the examination. Now, however, when a serious disease is suspected, the size and position of the stomach, and the presence or absence of tumors must be determined. By washing and siphoning, the duration of digestion is found out. The gastric secretion is collected, and the presence and amount of its inorganic acid and its peptic principles estimated by delicate chemical tests. The constituents of the urine are studied. It has been found possible to pass an instrument into the organ, and examine visually the condition of the mucous membrane. Quite recently a new œsophagoscope, invented by Professor Stoerk, of Vienna, enables one to make notes of the condition of the stomach's entering passage. With the means that have been devised for physical examination of the stomach, it is thus possible to learn with approximate exactness the character and activity of its secretions and the general anatomical condition of its walls. Already the treatment of gastric troubles by a few physicians abroad, who have been working in this line, has become based on objective phenomena, and has brought another division of internal medicine nearer to exactness. It is time that some American physicians take up the matter. We do not desire prematurely to promote the organization of an

association of American gastrologists, but simply to encourage an investigation and utilization of the exacter methods of studying the disorders of digestion. In this way the term dyspepsia will be abolished from scientific nosology. Whether the old-fashioned symptoms heretofore classed under that name will also be made to disappear, is a question which can be discussed in a later issue.

To those who are interested in this field of study we commend, besides the works of Leube and Ewald: Riegel, Ueber Diagnostik und Therapie der Magenkrankheiten, *Volkmann's Sammlung*, 289; also Ueber continuirliche Magensaftsecretion, *Deutsche med. Wochenschrift*, 1887, No. 29, and Beiträge zur Diagnostik der Magenkrankheiten, *Zeitschrift f. klin. Med.*, xii., p. 426. Cahn und v. Mering, Die Säuren des gesunden und kranken Magens, *Deutsches Archiv f. klin. Med.*, xxxix. Honigmann und v. Noorden, Verhalten der Salzsäure im carcinomatösen Magen, *Zeitschr. f. klin. SPINA BIFIDA OCCULTA.

The term "spina bifida occulta" was first employed by Virchow to denote a condition in which there is a defect in the arches of the vertebræ, such as is found in the ordinary spina bifida, but in which there is no external tumor. It is a condition which has been recognized only within a few years, the first authentic case of the kind, according to a statement of Mr. M. J. Bland Sutton in the *Lancet* of July 2, 1887, being one reported by Virchow in 1875. This case was discovered in the Pathological Institute of Berlin. The subject presented an unusual hairiness in the lumbar region. Examination showed that the hairy patch corresponded to a depression in the spine. The arches of the four lower lumbar vertebræ were incomplete, the resulting fissure being closed by a kind of fibro-cartilage. Virchow thought that the growth of hair was due to local irritation caused by the disturbance during the development of the spinal column. Other similar cases were afterward reported by Fischer, v. Recklinghausen, and Brunner.

In the article above referred to, Mr. Sutton relates an interesting case showing the relation, already noticed by Fischer and v. Recklinghausen, between spina bifida occulta and trophic disturbances. The patient was a girl, eighteen years old, whose foot had been amputated three years before on account of an ulcer of the foot with caries of the metatarsal bones. The affected member was also deformed, being in a position of talipes varus. The patient returned at this time for reamputation of the stump, which presented at its base an ulcer, about a quarter of an inch in depth, with callous edges. The case suggested spina bifida occulta to the writer, who accordingly made an examination of the spine. A deficiency was found in the arch of the third or fourth lumbar vertebra, and pressure at this point caused pain. There was an abundant crop of soft downy hairs in this region, radiating from the site of the deficiency as a centre. The author attributed the ulcer of the foot, the varus, and the ulceration of the stump to the spinal malformation. There were other interesting and important points in this case which we have not referred to.

It is evident that these cases offer a good field for research, for they have as yet received but little notice, and more extended study of them may throw much light on the subject of localized trophic disturbances. And, doubtless, now that Mr. Sutton has called attention to this affection, the number of cases observed will increase, and thus the opportunity for their study will be more widely extended.

ASIATIC CHOLERA AND THE NEW TEST FOR ITS BACILLUS.

The importation of a little cholera into this country just now is one of the minor evils connected with the present Italian immigration. It is too late in the season to fear any serious outbreak of the disease here, even if the quarantine measures were not so carefully carried out as they are. The interest in the cases brought to our port last week is therefore almost purely medical. It suggests the fact, however, that, fortunately, by private enterprise, we have now in this city several laboratories where the culture-test can be applied to any suspicious cases of cholera nostras that may be observed. There may be an opportunity also of testing the new chemical reaction attributed to the cholera-bacillus by Bujwid, and described by him in the *Zeitschrift für Hygiene* recently. Bujwid states that, after the addition of five to ten per cent. of ordinary muriatic acid to a bouillon-culture of the comma-bacillus, there develops in a few minutes a rose-violet color, which rapidly increases in intensity for half an hour. It then continues unchanged for several days. The reaction occurs in bouillon-cultures ten to twelve hours old, and in gelatine-cultures after twenty-four hours. Heat increases the coloring markedly. Bujwid claims that this chemical reaction is a special characteristic of the comma-bacillus of Asiatic cholera, and distinguishes it sharply from other similar forms of bacteria.

ALCOHOL IN HIGH LATITUDES.

In spite of the discovery of so many new remedies and the discussion resulting therefrom, the main battle of argument is still waged about alcohol. Commission after commission has contributed its decisions, and still the question is unsettled. Recent decisive testimony upon one phase of it, however, has been given by General Greely, of Arctic exploration fame, and his recent utterances in the *Forum* are most timely.

The last half-century has witnessed a marked reduction in the amount of alcohol supplied to men engaged in exploration in the high latitudes. The experience of previous years has finally made itself felt in official utterance. In one of the recent British expeditions, Sir Alexander Armstrong, Medical Director of the Navy, expressly counselled against alcohol rations for regular distribution, and advocated in their stead the use of cocoa and tea, but the officers in charge saw fit to allow the men two ounces of rum daily and double that amount during the absence of the sun.

One-fifth of the officers and over one-half of the men suffered from scurvy.

In Greely's expedition the amount of spirits taken was calculated on the basis of four ounces per man weekly. In the long period of exposure to which the latter party was subjected, it was indisputably shown that spirits given on the march impaired resistance to cold. Given in small quantities after the day's work was over, they distinctly stimulated the mental faculties, without any unpleasant effects. This small quantity was generally about two ounces. More than this seemed merely a waste. In the later history of the expedition, it was recorded that one-fourth of an ounce of pure alcohol, diluted with three times its weight of water, had an equally pronounced effect. It seemed to supply food and to have a decided alimentary value.

These results are what have been claimed for alcohol ever since its physiological effects have been critically studied. Their integrity has often been assailed by well-meaning but misguided enthusiasts, to whom anything concerning alcohol savors only of the powers of darkness. Upon them, all argument is wasted.

General Greely's observations are valuable additions to our knowledge concerning alcohol. The facts which they narrate were indeed known before, but they have now received an authentic confirmation, and that, too, under the most trying circumstances.

PSYCHIC MEDICATION.

The subject of hypnotism is one that is being continually brought to public attention, and of late with increasing frequency. We can remember when all the so-called hypnotic phenomena were looked at askance, and those who dealt with it regarded as more or less silly or knavish. The late Dr. Beard, who believed in the reality and scientific value of trance-phenomena, was publicly insulted by certain English physicians for venturing to demonstrate his views concerning the matter; and one of these physicians, Dr. J. Crichton Browne, was subsequently made honorary member of the New York Academy of Medicine.

Now, however, the subject is looked at with different eyes, and is deemed worthy of kindly notice by eminent men in all quarters. The public press has also been dwelling on the matter, and learned editorials upon the remarkable observations made by various foreigners are being emitted.

The investigations abroad, however, have, with one or two exceptions, added nothing to what was observed in this city five or six years ago. M. Luys recently appeared before the Paris Academy of Medicine, and reported the results of his experiments regarding the effects of drugs on the hypnotized patients.

M. Luys' communication, according to a correspondent of *The Lancet*, relates to the action of certain medicines upon hypnotized subjects by radiation, from the inside of hermetically sealed glass tubes. This interesting discovery, which dates, at any rate, from Hahnemann, was rediscovered by MM. Bourru and Burot, and related by them at the Congress of Grenoble, and they have since written a book on the subject. M. Luys has repeated and extended their experiments with eighty-six different substances, and finds that the effects produced upon the hypnotized organism by the action of the stimulating agents are of two orders. In one the subject is silent, and reacts as an automaton; morphine, strychnine, valerian, and sparteine produce phenomena of the kind. In the other the subject enters into the phase of lucid somnambulism, hears, and enters into communication with the outside world. This is effected by Indian hemp, coffee, alcohol, and various odorous substances. In the first series of experiments the subjects are placed in a state of lethargy. The sealed tube containing the medicine is put at the nape of the neck, and in a short time the face expresses a state of feeling—generally that of displeasure. In those who enjoy a dual personality (*sujets dédoublés*) the same substance will provoke an expression of suffering or malaise when applied to the right side of the brain, and a state of joy and expansion when placed on the left. Essence of thyme causes the submaxillary and thyroid regions to swell, the face to become turgescent, and the eyes to protrude. It must be noted that all this is recorded photographically. Morphia placed on the left side of the nape of the neck gives rise immediately to a feeling of terror. If the application is continued, the subject, actuated by the "instinct of protection," expresses the greatest anger. Upon changing sides and placing the tube behind the right ear, this subsides, and the face becomes calm and placid. Strychnia produces convulsions when applied on the left side; on the right, a state of gayety and "jubilation." To quote a last example: Valerian gives rise to emotions having a character of great sadness. "The subject," says M. Luys, "is under the influence of an irresistible impulse to scrape the earth. He kneels down to do so, and the idea comes to him that he is in a cemetery. He performs the exhumation of a beloved friend placing aside the soil with his hands and piously gathering together the remains. He makes a little mound, upon which he places a cross, and goes through the funereal ceremony with groans, genuflexions, crossings, and kissings of the earth!"

All this seems truly absurd. Yet it is stated seriously by a gentleman of scientific standing and undoubted ability.

We must refuse, however, to accept such statements until the experiments have been repeated on a larger number of persons, with every source of error excluded. The remarkable phenomena elicited from Parisian hystero-hypnotics have not been seen here.

EPISTAXIS AND THE LIVER.

Epistaxis is a symptom which has at different times such a widely different pathological significance that few writers attempt to discuss it, as if there were an independent disorder of this name. We find, however, that Dr. Alexander Harkin, of Belfast, Ireland, has put forth an essay in which he appears to find an autonomy and special pathologyuto plain nosebleed ("On the Nature and Treatment of Epistaxis," by Alexander Harkin, M.D., F.R.C.S.).

The author states that epistaxis may be dependent upon errors of circulation, *i.e.*, local anæmia or hyperæmia, or as a symptom of cardiac, renal, hepatic, or febrile disorders.

Very often the malady is indicative of a constitutional

disorder and of a disturbance of the physiological equilibrium of the blood-current. This constitutional disorder is, according to Dr. Harkin, in many cases an organic or functional disorder of the liver. It stands in the same relation to that organ as do hemorrhages from piles; and, indeed, the nose suffers from a kind of "facial hemorrhoids." Or, as it is put in another paragraph, epistaxis is a sign of a blood dyscrasis, itself a secondary result of a disordered liver. The indications, therefore, are to improve the condition of the blood and restore the health of the liver. For this purpose Dr. Harkin recommends chlorate of potassium alone or combined with iron, and large blisters over the liver. The use of blisters in this region for nose-bleed dates back to the time of Galen, and is supported by some French observers. Dr. Harkin himself reports several cases of intermittent epistaxis in which the symptom was relieved, and its return apparently prevented, by the use of the blister.

CONCERNING SOME CONTRIBUTIONS TO THE MEDICAL RECORD.

An esteemed correspondent, who evidently feels that he has a just grievance against The Medical Record, writes us a courteous letter setting forth his grounds for complaint, and asking for an explanation of the seeming discourtesy shown him. As the letter is a sample of many that have been from time to time received, we take the occasion to answer it here, trusting that all those who believe that they have not received the consideration which is due to them may accept it in lieu of a personal reply to their communications.

We will let our correspondent state his case in his own words. He writes: "Twice within the past half-year I have sent papers to your journal, on subjects which, you will pardon me for believing, were fully as important as most of those that you publish. The first paper, a pretty long one, was cut down from perhaps a page and a half to hardly thirty lines. The second one, a short account of a case, has not been printed at all, although four weeks have passed since I sent it to you; and it has not been returned to me either. Now I am a busy man, and don't have much time to myself, and I spent several evenings, when I was tired out after a hard day's work, in preparing those papers, and I was disappointed to see my hard labor thrown away. I have taken The Record almost from the time it first started, and these are the first articles I have ever sent you, and I feel as though you might have shown me a little more consideration. But, perhaps, because I live in the country you thought that what I had to say wasn't worth much. I think, though, if you will pardon me for saying so myself, that it was just as interesting as a good many of the things that the New York men write about in your journal."

We are sorry that our correspondent feels aggrieved; but, while sympathizing with him, we will try to convince him that he has not been unfairly treated. In the first place, if every communication received were to be published in full, The Medical Record would have to be enlarged to three times its present size, and even then there would be room for nothing but so-called original communications. Such a change would, we fear, be anything but gratifying to the masss of our readers. Very many of the communications which we receive, while containing much that is interesting, are too long, and may advantageously be condensed, not only in the interest of the readers, but in that of the author as well. Few men have the time or the inclination to wade through a long paper, unless they may be specially interested in the subject of which it treats; but they will read and profit by a short abstract of the same article. And it is the duty, oftentimes a disagreeable one, of the editor to decide which articles, of the many submitted to his judgment, can best be presented in abstract. When an author sends with his communication a specific request that the paper be published in full or not at all, his wishes are, of course, always respected, and if, in the judgment of the editor, the article is unsuitable for publication as it stands, the manuscript is returned to the author. This rule applies, however, only to papers of some length. We cannot undertake to return short articles which may not be suitable for publication. Again, it is impossible to publish every communication the instant that it is received. Each article must await its turn, and the editor must be allowed to decide upon the time of its appearance. All rejected communications, of any length, are returned as soon as possible after being read, and if an author hears nothing in regard to his paper for several weeks, he may be reasonably sure that it will be published in due time. Manuscripts occasionally, though rarely, go astray in the mails, and for such an accident the editor is, of course, not responsible.

As to the imputation that any discrimination is made against country practitioners, we can only say that the course of The Medical Record from its beginning is a sufficient refutation of such a charge. The country practitioner is apt to be a much more acute observer than his city brother, and his communications are always welcomed in our columns, and are, we venture to affirm, much less frequently rejected than are those written by physicians in New York or other large cities.

And while we are on this subject we may be permitted to say a few words upon the nature of many of the letters sent to the editor. There are many people who bother a journal uselessly with all sorts of questions and comments which are, and can be, of no possible interest to anyone but the writer. We do not now refer to letters of inquiry concerning medical facts or authorities, for a medical journal is supposed to have readier access to the sources of information on such subjects than individual physicians, but to other and wholly irrelevant matters. We not infrequently receive letters of complaint against instrument-makers, druggists, and others whom the writers accuse of having failed to keep their agreement in certain cases. Or, again, a physician will write for an opinion as to the relative standing of various drug firms, or to inquire concerning the reliability of a certain proprietary medicine. A little reflection will suffice to convince anyone that such questions are wholly beyond the province of a medical journal to decide. We sometimes receive elaborate articles, written evidently at the instigation of some enterprising manufacturer, in which some special form of pill or extract is recommended as being the only reliable preparation of the sort in the

market. We cannot, of course, be expected to lend our columns to advertising puffs of that nature. Finally, there are some who seize their pen on the slightest provocation, and write long articles on the most trite subjects, which could not be published without crowding out other more interesting matter, and which would only bore our readers if, as is hardly probable, they should try to peruse them.

We hope that none of our readers will misunderstand us, and suppose that communications from them are not welcomed. On the contrary, we are always glad to receive articles of the right sort from any of our contributors, and we esteem it an honor when they favor us with their communications. THE MEDICAL RECORD solicits good scientific papers from its many contributors, but it desires to be impartial, and is jealous of the interests of its readers as well as of its contributors, and it reserves to itself the right to use the articles with which it is favored (in the absence of directions from the author) in such a way as it deems will best serve the interests of all concerned.

News of the Week.

"LOVE'S LAMPOON."—Under this title, Dr. I. N. Love, in a recent column-interview published in a St. Louis paper, describes in poetic language the social splendors and scientific triumphs of the recent Congress at Washington. He then plays his fancy upon the doctors who, for their sins, have to live a trifle east of the Mississippi. These gentlemen, we are told, are continually expressing thoughts like the following:

"'We are the salt of the earth' and 'no good thing can come out of Nazareth,' the Nazareth in this case being the region west of the Alleghany Mountains. Some few of these provincial gentlemen have gone so far as to boast (among the number, the editor of the New York MEDICAL RECORD) that they have never been west of the range of mountains above referred to, and have no desire to take the trip. They laughingly refer to us as 'hayseed delegates' and as the granger members of the profession."

We have not the pleasure of knowing Dr. Love, but he evidently possesses a copiousness of feeling and a capacity for fanciful statement which promise a great future in the higher walks of fiction. We have never said, or boasted, or heard said, anything of the nature of the above. However, mere questions of fact ought not to be allowed to embarrass a truly epic imagination.

We trust that, some time, Dr. Love will come East, and see for himself how amiable and modest the medical gentlemen of this section really are; though, as to this, we shall cheerfully admit the superiority of our eminent critic.

SCARLET FEVER is epidemic in London.

THE FRENCH ACADEMY OF MEDICINE has made a report upon over-pressure in the public schools. It states that colleges and lycées should be removed to the country; that wide, open spaces should be set apart for games; and that class-rooms should be improved as regards lighting and ventilation. It also desires to see the courses of study simplified, but does not detail what, in its opinion, they should be. It does ask for an increase in the hours of sleep for young children; for all pupils a diminution of the time devoted to sedentary occupations, and a proportional increase in the hours for amusements and exercise. It insists particularly on the necessity of submitting all the pupils to daily exercise in physical training proportioned to their age.—*Sanitary News.*

THE AUTUMN CONGRESS OF THE SANITARY INSTITUTE OF GREAT BRITAIN was held on September 20th and following days at Bolton—the Right Hon. Lord Baring presiding. Dr. Russell Reynolds, F.R.S., presided over the Section of Sanitary Science and Preventive Medicine.

NOTIFICATION OF CONTAGIOUS DISEASES.—The City Health Board have voted to furnish postal cards to physicians of the city, properly inscribed, for the notification of contagious diseases. These will be supplied to physicians on application. All that the medical attendant will have to do on finding a case of contagious disease will be to fill out the card and drop it in the nearest post-office box.

OF THE MEDICAL RECORD'S REPORT OF THE INTERNATIONAL MEDICAL CONGRESS the *American Practitioner and News* says: "Dr. Carpenter, who superintended the work for THE RECORD, performed his task so quietly and unostentatiously that one might easily have concluded that the undertaking had been abandoned. But the full, accurate, and well-arranged reports that have reached us not only dispel any such doubts, but characterize Dr. Carpenter as one of the most capable journalists, medical or secular, in the country."

DR. ST. JOHN ROOSA'S TREATISE ON THE EAR has been translated into German by Dr. Ludwig Weiss, and will soon be published in Berlin by August Hirschwald.

DR. MARY T. BISSELL has been appointed attending physician to the Babies' Ward of the Post-Graduate Hospital.

THE NEW YORK STATE MEDICAL ASSOCIATION held its annual session during the past week. The attend-

having become caught under the head of the drainage-tube. The obstruction was relieved and a longer drainage-tube inserted.

In a third case in which he had introduced a drainage-

in London.

A PERMANENT MEDICAL CORPS.—The Centennial Volunteer Medical Corps effected a permanent organization at their headquarters in the City Hall, Philadelphia Pa., on Monday, September 26th. About thirty members were present, and these officers were chosen: President—Dr. J. C. Cleborn, United States Navy; Vice-President—Dr. T. H. Andrews; Secretary—Dr. G. M. Bradfield; Recording Secretary—Dr. Thomas S. Price; Treasurer—Dr. T. S. K. Morton. A committee consisting of Dr. Brinkman, Dr. Henson, Jr., Dr. Grayson, Dr. Christie, Dr. Coplan, Dr. Ashborn, Dr. Baldy, Dr. Kyneet, and Dr. Hammond were appointed to frame a constitution and prepare bylaws. The object of the organization is to perpetuate the pleasant relations between the members of the corps and to furnish the city with a good medical service in time of need. The Committee on Constitution and By-Laws met on the evening of Tuesday, September 27th, at the same place.

PROGRESS.—The Cooper Medical College now requires for graduation attendance upon three full medical courses. A matriculant examination is also required of those not possessing certain prescribed evidence of general education.

COMMENTS ON THE CONGRESS.—The gentlemen who came from abroad had a right to expect to come to a representative American gathering; and this they failed to find. Sectional as regards residence, scant in men of recognized professional eminence, the American contingent of the Congress was a body of very worthy family doctors. The whole registration, by the Secretary-General's count, was 2,700, which means an actual attendance of between 2,000 and 2,500. The number of foreign members was not far from 150; and of these there were but few of wide fame. As to the papers presented, quantity, not quality, seems to have been the rule.—*Cor. Boston Med. and Surgical Journal.*

In more than one respect was the Ninth International Congress a success. Some of our visiting confrères from Europe say that from a scientific standpoint no Congress ranks higher, and that the proceedings, when published, will reveal a wealth of learning among Americans of which the profession generally in Europe has been entirely ignorant.—*Journal of American Medical Association.*

CONGRESS AT AMSTERDAM.—There is to be a Congress for the discussion of Natural Science and Medicine at Amsterdam, on September 30th and October 18th. There will be four sections: 1. Physics and Chemistry, under the presidency of Professor Vandesande-Buckhuyzen. 2. Natural History and Biology; president, Professor T. Engelman. 3. Medicine; president, Professor Donders. 4. Geology and Geography; presidents, Professors Martin and Kan. This is to be essentially a Dutch Congress, but invitations have been sent to scientists and medical men belonging to the Flemish parts of Belgium.

ONE OF THE DRUGGISTS of the city announces that he [illegible] weeks have passed since I sent it to you; and it has not been returned to me either. Now I am a busy man, and don't have much time to myself, and I spent several evenings, when I was tired out after a hard

IS THIS A SLANDER?—The *Rio News* publishes the following item: "The medical men of the United States will soon have an opportunity to see the celebrated Dr. Domingos Freire, and to investigate his claims as discoverer of the yellow fever microbe. It will be well to ask the doctor for his microscopic slides, preparations, and other proofs, and not accept his statements as proofs of the discovery. There are many people here, and a majority of the leading Brazilian physicians among them, who consider Dr. Freire's discovery a humbug." We believe that Dr. Freire has shown his slides and other preparations, and given evidence of scientific knowledge and technical skill.

ANTISEPTIC CIGARETTES for fumigating the naso-pharynx have been devised by Dr. H. Macnaughton Jones. After some experiments, his chemists prepared four different forms: No. 1, containing eucalyptus and iodoform disguised with vanillin. No. 2, eucalyptus with iodosalicylic acid. No. 3, coltsfoot with eucalyptus and iodoform disguised with vanillin. No. 4, tobacco, eucalyptus, and iodoform disguised with coffee. Each cigarette contains one grain of the active ingredient. Dr. Jones adds that the iodosalicylic acid has not the unpleasant odor of iodoform and other iodine compounds. While it is quite as effective on the lower forms of life, under combustion iodine is evolved. All the cigarettes will be found pleasant to smoke, and the odor of the iodoform well disguised, while its presence in the nasopharynx for some time after the cigarette is used may be detected by its taste. Those made with tobacco, eucalyptus, iodoform, and coffee are particularly agreeable, and the odor is thoroughly disguised; so indeed is it with those made with vanillin, and the coumarin yielding an aromatic vapor which is pleasant rather than otherwise. Half a cigarette is sufficient to smoke at one time. Three in the day are not too many, though the number must be regulated by the prescriber.

A NUTRIENT SUPPOSITORY, of two drachms weight, is equal to three ounces of beef-tea, and is more convenient to use.

THE FOREIGN DELEGATES.—Outside of Great Britain there were sixty foreign delegates to the International Congress. Germany sent seven, France fourteen, Austria two, and Italy four.

MR. STEVENSON'S EULOGIUM OF DOCTORS.—Mr. Robert Louis Stevenson, who has recently come to this country on a visit, and whose remarkable work, "The Strange Case of Dr. Jekyll and Mr. Hyde," has been so successfully dramatized here, is an invalid, and has had a good deal to do with doctors. His recently published book, "Underwoods," is dedicated to "a few out of many doctors who have brought me comfort and help," and he adds a eulogium upon the profession which we think will be read with pleasure. "There are," he says, "men and classes of men that stand above the common herd; the soldier, the sailor, and the shepherd not unfrequently; the artist rarely; rarelier still the clergyman; the physician almost as a rule. He is the flower (such as it is) of our civilization; and when that stage of man is done with, and only remembered to be marvelled at in history, he will be thought to have shared as little as any in the defects of the period, and most notably exhibited the virtues of the race. Generosity he has, such as is possible to those who practise an art, never to those who drive a trade; discretion, tested by a hundred secrets; tact, tried by a thousand embarrassments; and, what are more important, Heraclean cheerfulness and courage. So it is that he brings air and cheer into the sick-room, and often enough, though not so often as he wishes, brings healing." Mr. Stevenson is a nephew of Dr. G. W. Balfour, Vice-President of the Royal College of Physicians of Edinburgh, so well known by his excellent work on "Diseases of the Heart."

A BLOW TO THE PATENT MEDICINE BUSINESS IN GERMANY.—It is stated that the advertising or sale of patent medicines (secret or proprietary preparations) has been absolutely prohibited in the German capital, and sixty-one of them have been publicly denounced on account of disclosures made by chemical analysis.

Reports of Societies.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, June 3, 1887.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

FRIEDREICH'S DISEASE, OR HEREDITARY DEGENERATIVE ATAXIA.

DR. C. L. DANA, in presenting a case of Friedreich's disease, said there had been reported altogether but a few more than one hundred cases, and they were limited to twenty-one or twenty-two families. America had contributed its full quota of that number. Two of the best papers on the subject had been contributed by physicians in this country—Dr. Everett Smith and Dr. Kellogg.

The patient presented was nineteen years of age; his family history was negative. His father was probably a dissipated man. The patient, so far as could be learned, had had no disease until he was fifteen years old. He had had no bad habits; had no venereal disease, and had not indulged in venery. Two years before his symptoms appeared he had had a fall and struck the back of his head.

About two years ago he began to have constant thirst, and to suffer from a feeling of unsteadiness; he reeled in his gait; the speech became somewhat affected. Being in the hospital, he was referred to Dr. Dana four or five months ago by Dr. Gouley.

He found the patient suffering from marked ataxia, and that he reeled a great deal in his walk; could not stand with the eyes closed, and there was some ataxia in the arms. There was a slight amount of weakness of the muscles. At times he was dizzy; his legs felt heavy and numb occasionally. There was no pain. The patellar tendon-reflex was normal. There was a slight degree of anæsthesia on the outer part of the legs. There was some muscular anæsthesia. The patient complained a great deal of thirst. The specific gravity of the urine was 1.002; quantity, one hundred and fifty to one hundred and eighty ounces a day; no sugar. There was no emaciation, no disturbance of the sphincters. There was some tendency to talipes equinus, slight curving of the spine, some oscillation of the head, and a slight amount of nystagmus. The symptoms were those of pronounced ataxia, very slight anæsthesia, polyuria, disturbance of speech, and head oscillation. The speech was somewhat thick, slow, and scanning. The hands and feet were cold and reddish. The boy had improved very much when presented.

The case was interesting, in the fact that it presented some rare features. Polyuria in hereditary degenerative ataxia was a rare thing, although it had been observed in one case at least. The presence of the patellar tendon-reflex was unusual but not unique. The disease resembled very much locomotor ataxia, but differed from it in the absence of severe pain and severe sensory troubles, also in not having much disturbance of the bladder and rectum, nor optic symptoms, except that there was generally nystagmus. This boy had little, if any, nystagmus.

Pathologically there was found in Friedreich's disease sclerosis of the lateral and posterior columns, and the cord was usually less perfectly developed than normal.

In reply to questions, Dr. Dana said that patients with Friedreich's disease sometimes lived thirty or forty years, but after a time there developed more or less paralysis, the legs became cramped and distorted, and there might be complete paralysis.

DR. E. G. LORING remarked that while the patient was waiting he had looked into his eyes, and found that the fundus looked very much as it often did in commencing optic atrophy. The arteries were very small and the veins very large.

DR. V. P. GIBNEY said that in looking over the histories of some cases, in the Forty-second Street Hospital, which used to be called cases of spastic contracture, he found that of a boy whom they called Jumping Jimmy. This was about eleven years ago, and he was then ten or twelve years of age. At that time he had been in the hospital three or four years. His speech was that of ataxia; he had so marked ataxic movements that he could with difficulty walk across the floor. Except that it was more marked, the ataxia was like that in Dr. Dana's case. He suffered no pain, and was unable to give any cause for the disease. He was transferred to Randall's Island Hospital, where, when seen by Dr. Gibney, three or four years ago, he remained in about the same condition.

DR. POLK asked Dr. Dana if he thought there was any relation of the fall, in the case of his patient, and the ataxic symptoms.

DR. DANA thought the fall might possibly have been an exciting cause.

REMARKS ON IMPERFECT DRAINAGE AFTER LAPAROTOMY.

DR. W. M. POLK related three cases bearing on the question of drainage after laparotomy. The first case was one of ordinary pyo-salpinx. No symptoms developing, he removed the drainage-tube at the end of forty-eight hours, but, contrary to his usual custom, he did not follow its withdrawal by a smaller rubber drainage-tube. The recti muscles were unusually taut, and closed the orifice, which ordinarily remains open several days after withdrawing the tube. Accumulation took place, and within twelve hours the temperature rose to 103° F., and the pulse to 120. On the third day Dr. Polk opened the abdominal cavity, washed it out thoroughly with warm water, put in a drainage-tube, and continued the irrigations for a week.

The second case was one in which immediately after the operation the woman began to vomit. This was supposed to be due to the effects of the ether. There was not much elevation of the temperature or pulse, but the vomiting continuing Dr. Polk became convinced there was some obstruction. He therefore removed the drainage-tube, washed out the cavity with a solution of bichloride of mercury, 1 to 10,000, introduced his finger, and tore up all adhesions binding down the intestines. He finally found the point of obstruction, a coil of intestine having become caught under the head of the drainage-tube. The obstruction was relieved and a longer drainage-tube inserted.

In a third case in which he had introduced a drainage-tube, but had failed to irrigate the cavity, the temperature rose, and no discharge took place from the tube. About the third day he took out that tube, introduced his finger to the bottom of the cavity to free obstructions, introduced another tube, and thoroughly irrigated the cavity. It was about two weeks before the patient was beyond danger.

All three of these patients recovered; all three would have died had he not interfered. Still, there was a difference of opinion among gynecologists as to the advisability of reopening the wound under these circumstances and washing out the cavity, some claiming that the washing process was likely to spread abroad the infecting matter and increase the chances of general peritonitis. But his experience in these three cases had been such as to firmly impress him with the advisability of prompt interference in all cases of like kind.

THE PRESIDENT said that, if he remembered correctly, the principle just asserted by Dr. Polk was strongly advocated by Dr. Peaslee fifteen or twenty years ago. As illustrating the marked tolerance of the peritoneum in ovariotomy, he cited a case in which, two years ago, a colloid tumor burst, discharging its contents throughout the abdominal cavity, and he was compelled, in order to

cleanse the cavity thoroughly, to displace all the intestines, making literally an ante-mortem examination. He then introduced a drainage-tube, sewed up the wound, and at the end of ten days the patient was sitting up in a rocking-chair. She made a perfect recovery.

POTT'S DISEASE—A QUESTION OF DIAGNOSIS.

Dr. V. P. Gibney gave the history of a case of Pott's disease, in which there had at times been a question whether the symptoms were due to the disease of the spine or to the morphine-habit. The patient, a woman, now aged thirty-five years, began eight or nine years ago to show signs of Pott's disease. There was pain from concussion during riding, etc., but there was scarcely any deformity. She was then treated with the plaster-of-Paris jacket in this city; her symptoms were relieved, and after three or four months the jacket was removed. From that date until two years ago she had recurring attacks of this kind, lasting a month or two at a time. She was scarcely able to walk because of pain and jerkings in the hamstring muscles. After this period she began the use of morphine. Dr. Gibney saw her in September, 1885. She was at that time taking from three to five grains of morphine, hypodermatically, daily. He hesitated to pronounce the case one of Pott's disease, although from the previous history of the case he thought it must be, and began treatment accordingly. He applied a movable corset, made frequent cauterizations of the spine, gave drachm-doses of the iodide of potash three times a day, etc. She recovered the use of her limbs within three months so that she could walk about the house, but there still remained contraction of the hamstring. He did not succeed in correcting the morphine-habit until the spring of 1886. From that time until a few weeks ago she was not under any special treatment. She had worn the jacket, taking it off, however, when she felt like doing so. She thought she was not getting much better so far as anæsthesia was concerned, and she occasionally had pains. About a month ago, after riding some distance, the pains came on in increased severity, and suddenly she lost the use of her lower limbs, was unable to void the urine, and the bowels were sluggish. There was complete abolition of sensation and motion below the knees on both sides. Even the strongest faradic brush, when applied to the outer side of both legs, caused no feeling. But on the inner side there was slight sensation. There was now a slight knuckle at the level of the second or third lumbar vertebra, together with excessive tenderness and soreness.

THERE WAS CYSTITIS.

She came of a tuberculous family.

All the patient's symptoms at present pointed to an excessive amount of exudation about the lumbar vertebræ, with pressure upon the nerves.

A QUESTION OF DIAGNOSIS.

The President related the following case, which he saw in consultation with Dr. A. M. Campbell, of Mount Vernon, N. Y., and queried as to the diagnosis: Two years ago a young man, twenty-five years of age, of scorbutic habit, had an enlarged inguinal gland on the right side, which suppurated, was opened, and healed in due time. This was followed in the course of a few months by two others, which were treated in the same manner. In the meantime pus was discovered in the urine, amounting to ten or fifteen per cent. by quantity. The specific gravity was 1.025. The urine contained a few waxy casts. The lower limb on that side became contracted. Two months ago a swelling appeared over the trochanter which gave a succussion sound, as if it contained air. There also existed a sinus the origin of which was not evident. Dr. Shrady, with the assistance of Drs. Campbell and Brush, subsequently opened a large, burrowing, fetid abscess of the hip, one portion of which lay in contact with the rectum. Through drainage was established, with relief of all the bad symptoms.

It was a question whether pyo-nephrosis or sacculated abscess of the kidney preceded the difficulty. At the commencement of his illness, two years ago, the patient had passed a urinary calculus.

Dr. Shrady found it difficult to trace a possible connection between the glandular abscesses in the groin, the pus in the urine, and the abscess on the hip. The abscess on the hip might be explained by the burrowing of pus beneath the fascia, but he was unable to understand why it should contain gas. The temperature during the past two months had been 101° F. in the morning and 102° in the evening. The patient had lost considerable flesh. There was no disease of the spine. The liver was normal. There was no unusual dulness in the region of the kidneys. There was contracture at the hip and thigh, which could in part be explained by the patient's forced position during a long illness. The discharge from the sinus did not exceed a teaspoonful during the twenty-four hours.

One surgeon had suggested that the trouble came from the kidney and advised extirpation, but Dr. Shrady opposed it, and said that probably whichever kidney should be removed it would prove to be the wrong one. There was no cystitis.

There was an antecedent condition of some interest. There was a tumor low down in the right hypogastrium, which on percussion gave dulness. It was painful. The surface above was œdematous; the thigh was flexed. These symptoms continued two weeks, at the end of which time the patient had a free evacuation of the bowels, the fecal matter containing a quantity of grape-seeds and pus. There had probably been enterocolitis, due to an irritating substance in the caput coli.

SUDDEN BLINDNESS OF UNCERTAIN ORIGIN.

The President related the history of a case of sudden complete blindness in a lady fifty-four years of age, a sufferer from gall-stones. She was a patient of Dr. Dawes, of Saugerties, N. Y. The blindness occurred suddenly during an attack of vomiting on April 24th. There was no paralysis of any muscles; the pupils were mobile; there seemed to be some confusion of ideas. At the end of three days the perception of light began to reappear in both eyes. The diagnosis was made of intra-cranial effusion or clot located behind the optic chiasm, probably in the quadrigemina tubercula. The patient was able to read with her ordinary glasses at the end of two weeks, and subsequently entirely recovered.

Dr. Loring thought the case was rather a remarkable one, especially as both eyes were affected. The fact that the blindness occurred suddenly during an attack of vomiting would point to hemorrhage either into the sheath of the nerve or about the corpora quadrigemina. If there was hemorrhage into the sheath of the nerve, one would suppose, instead of complete blindness in both eyes, that there would be some limitation of the field. There would also be ophthalmoscopic signs. As to cerebral disturbance, that might have been apparent only. He had seen cases of sudden blindness produce such a marked nervous impression that at first one would have suspected cerebral trouble. He felt quite sure that in Dr. Shrady's case there was not cortical hemorrhage nor a large hemorrhage at the base.

The President remarked that he carefully tested the field of vision, and that a candle was imperceptible in a dark room.

Dr. Dana asked Dr. Loring whether such a condition was ever produced by hysteria.

Dr. Loring replied that it might be hysterical.

A CASE OF VERTIGO DUE TO CHRONIC AURAL CATARRH.

Dr. Samuel Sexton related a case where the aural symptoms were the first to attract attention in a gentle-

man broken down with overwork. The patient was over forty-six years of age, and had been uninterruptedly engaged on a newspaper for over twenty-five years; for a long time as editor of a daily paper, where the literary work was arduous. Being naturally of a strong constitution, the severe mental strain has only told on his health during the past ten years. He has finally become so decidedly neurasthenic during the past three years that he gets through his labors only by a strong effort of the will. Food no longer digests well, and the bowels are sluggish. He was always excitable in disposition, but now is excessively so, the nervous strain fluctuating between great irritability on the one hand and extreme despondency on the other. For the past five years there has been a constant feeling of occipital soreness, and of late, headache, confined to the vertex, has been experienced. Sometimes nervous excitability is so great that an inclination to jump out of the window is felt. The act of coitus is attended with "terrific" excitement and followed by extreme exhaustion. The convivial use of stimulants, to which he was moderately addicted, is no longer tolerated. He thinks that a severe shock occasioned by an accident ten years ago, from which he was unconscious for ten minutes, may have left some permanent effect, though this is by no means certain.

In consequence of this physical deterioration, he has been for the past eight years unable to perform mental labor as before and there has been also a gradually increasing susceptibility to exposure, so that he is seldom free of head-catarrh. On two occasions, once four years ago and again eight months ago, the ears were very much affected by

AN INVASION OF THE CATARRHAL INFLAMMATION,

especially on the left side. He thus became painfully aware of a defective state of the hearing which before had only been suspected. Very distressing subjective phenomena remain in the left ear, the organ feeling numb, the voice and respiratory movements autophonous, while "echoes" and "a noise like a sea-shell" are never absent. Similar symptoms are beginning to be experienced also in the right ear.

Sudden changes in the position of the head, as well as meteorological variations, exert an unfavorable influence in giving rise to these symptoms. Sometimes, by gently inclining the head backward, or by traction on the auricles, auditory tension is temporarily re-established and relief obtained. But on suddenly rising up or stooping down vertigo is experienced, and it often becomes necessary to catch on to something for support.

Hearing, at all times defective, varies with the tension of the transmitting mechanism. Ordinarily he distinguishes a conversational tone in the right ear, at a distance of twenty feet, but with difficulty in the left. It is notable in these cases, where nervous exhaustion is marked, that perception of sound is defective, persons frequently being seen who say they are "slow of hearing."

The general deterioration of the mucous membrane is well shown in the fundus of the ear in these cases—often before attention is attracted to the mucous surface elsewhere. Examination of the drum-heads in this case gave evidence of an advanced stage of aural catarrh. Their brilliancy was gone, as was the normal polish, having given place to the glazed appearance of porcelain. The posterior segment of the right membrane was more opaque than the anterior segment. In the left, however, the changes were more marked, the entire membrane having a somewhat glossy look. The condition of the mucous coat on both sides imparted a humid aspect to the dermic surface and the left drum probably contained fluid which might account for the altered resonance on that side. There was a small area below the umbo on the left side seemingly much thinner than the surrounding tissue, and, moreover, the range of oscillatory movements on this side was much increased.

Dr. Sexton was disposed to think the vertigo was due to the withdrawal of the normal tension of the drum of the ear, whereby

LABYRINTHINE FLUID BECAME SUBJECT TO SUDDEN VARIATION.

This, in a neuropathic subject, like the one under consideration, would seem sufficient to account for the symptoms described.

The patient had obtained no permanent relief from treatment, and the increasing vertigo and nervousness, threatening soon to incapacitate him for business or enjoyment of life, had caused great depression of spirits, not to say alarm.

We can usually make a favorable prognosis in these cases, reassuring them in respect to any fear of serious brain-trouble; and, by means of treatment directed to the aural catarrh, together with proper rest from mental efforts, out-door life, etc., a cure may be confidently expected. Frequent interruptions in work and change of scene are necessarily a part of successful treatment.

Dr. C. L. Dana thought that probably in many of these cases there was hyperæsthesia of the nerves which supplied the semicircular canals, and that the change in the position of the head, which ordinarily did not stimulate these nerves unduly, did so in this state. That, it seemed to him, would be a more plausible explanation than to suppose excessive impact upon the oval foramen, because if, in this condition, excessive impact would cause vertigo, loud explosions ought to do so in the normal condition of the ear.

Dr. Sexton said he did not know exactly what Dr. Dana meant by hyperæsthesia of the nerves. Did he mean of the nerves which took cognizance of sound?

Dr. Dana replied that nerves going to the semicircular canals did not take cognizance of sound alone, but that they also had much to do with equilibrium, or adjusting the body in space.

Dr. Sexton had received the impression from reading the literature of the subject that the ground taken by some that the nerves in the semicircular canals had anything to do with preserving the equilibrium of the body had not been sustained. In respect to the effect of aerial impact from explosions and loud sounds, of course they may give rise to shock in the normal state of the ear, but the transmitting mechanism prevents inward excursions of the drum-head causing this ordinarily.

The Progress of Medical Education.—We desire to return our most cordial thanks to the secretaries of the various medical colleges of this country who have up to this date so kindly furnished us with copies of their several announcements for 1887–88. The announcements for the coming session are quite up to those of past sessions. In some instances, indeed, we observe marked improvement in the typography and the quality of paper employed, and we note with pleasure this evidence of the advancement of the cause of medical education. Let the good work go on.—*Medical Age.*

The Late Dr. Gross on Valentine Mott.—Dr. Gross in his memoirs says: "As a public teacher Mott long occupied a prominent position. His lectures were essentially devoted to operative surgery, and exhibited the results of his rich personal experience, but they were always far in arrear of the existing state of the science. Another feature of them was their egotistical character. He could not help talking about the ligation of the innominate artery, the excision of the clavicle—styled by him his "Waterloo operation"—and other feats, the record of which, however amusing it might have been for a time to young students, could not fail sooner or later to become tiresome, if not offensive. This was Mott's weakness. If he possessed a certain degree of strength as a teacher of operative surgery, he was at fault as a teacher of surgical pathology—a fault shared until recently by most of the professors of this branch of science in our medical schools.

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

VICHY AND ITS MINERAL WATERS.

PARIS, September 16, 1887.

WHEN a physician settles down at a watering-place, he generally publishes a book on the composition of its mineral waters and the diseases for which they are indicated, notwithstanding the numerous works that may be in existence on the same subject. Each new-comer feels the necessity for producing a work of his own, and this has induced Dr. C. E. Cormack to publish a work of this kind. In the present case the reason given by the author for so doing is, that while a great number of French works have been written upon these waters, there are comparatively few English ones on the same subject; he therefore hopes to render a special service to his countrymen by placing before them, in a work in their own tongue, the great advantages to be derived from these waters. He, moreover, states that, while the number of visitors to Vichy, representing every nationality, has of late years been steadily increasing, the number of English tends to decrease, and is considerably less than it was ten years ago; but why it should be so the author is unable to say. The work is divided into two parts, the first giving a description of the various springs (thirty-one in number) and the diseases in which they are generally found beneficial. The second part gives all the necessary information respecting the means of reaching Vichy, with a description of the town itself, the thermal establishment, and the different places of interest in its environs or within easy reach of it. The author professes to have composed this work, "not so much for the medical profession as for the public," and he adds, "we have endeavored to explain in popular language where the thermal treatment is indicated, and how the waters operate." The desirability, however, of writing on medical subjects for the general public may be questionable, for, however clear and explicit the style may be, they would be calculated to confound rather than benefit the patients who would read them.

The author states that the mineral springs of Vichy are all closely allied in composition; they are alkaline, and contain on an average five grammes of bicarbonate of soda per litre, the difference in the springs consisting in their varying slightly in composition, but more particularly in temperature. He gives the analysis and temperature of each spring, and also the individual indications, and tells us in a general way why the preference should be given to one spring rather than to another in certain diseases, or during certain complications of these diseases; and to the question as to how, if the waters of the various springs are almost analogous in their composition, they should be suited for such a variety of diseases, the author cites M. Lucas, who in writing on the subject says: "The Vichy waters present a far more important difference in their therapeutic uses than one could have supposed from their chemical analysis, and although it is difficult to show *à priori* the reason of these differences, numerous observations, repeated during twenty-three years, leave me without a doubt on this point." The author warns patients against the use of artificial Vichy water, which, he says, "can in no wise replace the genuine water, the only salt it contains being the bicarbonate of soda; and while it may do good to a certain extent, it cannot act as the genuine water does, with its numerous mineral ingredients so intimately connected and in such a perfect state of dissolution. The natural mineral water has all the soda it contains absolutely in the bicarbonated state, whereas this salt in the artificial water is not completely saturated, and is also found as a neutral carbonate and a sesquicarbonate. In a word, the artificially prepared water acts simply as an alkaline solution, and has no connection with the natural water." There is a popular notion, not only among the general public, but also in the profession, that the treatment at watering-places should not exceed twenty-one days. The question why twenty-one days should be fixed upon, and not more or less, has often been asked, and whence the origin of the idea. This the author explains in his book and states that this period is not absolute, as each individual case should speak for itself, and adds that on an average twenty-one days may be sufficient, but that another twenty-one days may be necessary later on in the season.

But, as Dr. Cormack suggests, even then it by no means follows that the treatment is over. As the treatment has to be cautiously commenced, so must it be cautiously dropped. It is usual to have the waters ordered yet for some little time for home consumption, to insure the therapeutic effect of the waters. The cold springs are always those which are recommended. Lists are given in the book of the cold and hot springs. There are two maps with the book, one of the town and the other of the environs of Vichy. The author states that he avoided encumbering the map with too many names, thus taking away from its clearness; and for the same reason omitted the mountain-ranges. The book is also furnished with a good index, and will be found of value, as it gives much useful information respecting Vichy and its waters.

AN INGENIOUS METHOD OF REMOVING NASAL POLYPI.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: All surgeons who have had experience in removing polypi from the posterior parts of the nasal cavities, and from the upper pharynx, must have met with cases in which it was a difficult matter to get the loop of the wire snare in position, especially when the growths were large. An expedient which I employed recently in such a case may prove of value to others. The patient had not breathed through either nostril for eleven months, and when seen by me for the first time the polypus was found, by the aid of the rhinoscopic mirror, to be growing apparently from the right nasal cavity, projecting into the upper pharynx, partly filling it, and lapping over the septum so as to obscure the view into the left cavity. It could not be seen from the anterior nares on either side, even after the use of cocaine. Its site could not be determined with accuracy, but was found afterward to be on the external wall of the right cavity. This was somewhat contracted anteriorly, and the amount of space available in which to work was limited. A four per cent. solution of cocaine was applied, and the platinum-wire loop of a snare-apparatus, connected with a galvano-cautery battery, was insinuated through the nostril, past the growth, and into the pharynx. But the wire was so small and pliable, and the polypus so large, that after trial it seemed impossible to get the loop caught around it. I failed with instruments guided by the mirror, and also with the finger hooked up behind the palate. The difficulty would have been much the same with the steel wire of the cold snare. I then took a rubber tube, two feet long and $\frac{1}{12}$ inch in diameter, outside measurement, and threaded through it a piece of platinum wire of still greater length, leaving some of it protruding from each end. This was doubled, and the loop was pushed through the nasal cavity into the pharynx by means of a small straight throat-brush, the hairs of the brush being parted so as to act as a fork. The rubber tube being much easier to manipulate than the wire alone, owing to its elasticity and greater size, it was not difficult to get the tumor engaged in the loop by the use of the finger. The loop was drawn snugly around the pedicle, one end of the wire was held fast, and the tube was gradually pulled out of the nostril, slipping over the wire and off

the other end, leaving the wire in place. The double copper tubes were then taken from the handle, the short wire previously used having been removed, and the ends of the long wire were passed through them, and the tubes slipped down the wire into the nasal cavity as far as they would go. The handle was attached to the copper tubes, the wire tightened, the circuit closed, and the pedicle cut through in the ordinary way. The polypus was about the size of a large walnut. The presence of an assistant was of value in the manipulation.

KEMP P. BATTLE, JR., M.D.

RALEIGH, N. C.

THE FACILITIES FOR A GOOD MEDICAL EDUCATION IN COLORADO.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your editorial notice of the "Gross Medical College," of Denver, Col., of July 23d, is hardly correct. You say that Denver is a city of eighty thousand inhabitants, and that the whole State has but two hundred thousand and only two medical colleges. "It plainly needs a third." For fear that your remarks might spur up some energetic doctors to actually start another, permit me to say that the "Gross Medical College" is that third. About seven years ago the Methodist "University of Denver" started a medical branch, which is now in operation. Four years ago the regents of our State University started a medical branch at Boulder, a town of three thousand inhabitants, thirty miles from Denver. This is in operation, and we may say successful operation, for it has never refused a diploma to any person putting in two terms. Its enemies—and what good projects do not have enemies?—point to the report of the joint committee of the last State Legislature, which condemned it and recommended its discontinuance, as being a school whose diplomas would not be recognized; but that report, we are happy to say, had no weight with the regents, over whom the legislature have no control. And that the school has not had a dozen medical clinics since its conception, and has no charts, casts, manikin, skeleton, wet or dry specimens, or, in fact, any other apparatus to teach with, should, we think, not be used against the school, but rather as an evidence of the earnestness of purpose of the regents.

The malicious hints of its detractors, that the school is run to furnish salaries for the brothers, aunts, and cousins of the Board, we are pleased to report is without foundation. It really is a *bona fide* institution, which every tax-payer can prove by the items in his tax-receipts, and that is more than either the Gross Medical or the Denver Medical College can say.

FAIR PLAY.

NOTES ON THE TREATMENT OF TYPHOID FEVER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Learning from the medical journals that the mortality from typhoid fever in Eastern and foreign hospitals still ranges from six to fifteen per cent., I thought it might not be uninteresting to give a *résumé* of my last ninety cases, treated without a death. This report has been delayed, hoping that the number might be increased to one hundred, but the introduction of artesian water for all purposes, and the improved sanitary condition of the city, have practically stamped out the disease, apparently at least, for the present. My list would already be one hundred, should I exclude two cases of death for which I was hardly responsible. One of these had been ill for ten days before I saw her, and died from perforation of the bowel within twenty-four hours; the other had been ill a few days and had a profuse hemorrhage from the bowels the night before I was called, and died without rallying, from collapse.

The mortality of typhoid fever in Northern Illinois twenty years ago was about twenty-five per cent. under the treatment of quinine, turpentine, and laudanum emulsion, etc., and still remains large when treated by the old methods, but has been reduced to four or five per cent., and even less, by recent methods, and, in fact, cases give us comparatively little trouble or anxiety. I have treated several cases in the country that I was unable to visit more than twice, and some I have not seen at all, where I had recently attended some other member of the family, and they were intelligent enough to report from day to day the temperature, pulse, and general condition of the patient. These cases might be arranged in three series, so far as treatment is concerned, of about thirty each—the first being treated by cold baths or packs with but little medicine; the second by salicylate of soda; the third by antipyrine and antifebrine. As the results, so far as recovery is concerned, have been uniform in each series, and other characteristics and symptoms have been so nearly parallel, I will not take your valuable space in detailing the observations on each series, but deal with them in the aggregate.

Of these 90 cases, 67 were males, 23 females; the oldest male was aged sixty-three, and youngest male aged four; the longest duration of disease (four patients), forty-two days; the shortest duration of disease, fifteen days; number of relapses, six; average duration of relapse, sixteen days; average duration of all cases, twenty-five days. Twenty-four cases began with chills, vomiting, etc., and were prescribed for as remittent cases at first; 69 cases had epistaxis; 5 had slight hemorrhage from bowels before the thirteenth day; 53 cases had diarrhœa (7 troublesome); 5 were ambulant typhoid, never taking to bed (yet with temperature of 103° to 105° F., and duration of three weeks); 67 had sore spots. Those without sore spots were under ten or over forty; 7 were complicated with pneumonia (latent); 17 were complicated with bronchitis; 21 were complicated with albuminuria (a larger per cent. treated with salicylate of soda being affected than with other treatment); 23 required laxatives; 14 had no disturbance of bowels; 37 required hypnotics; 71 had hydrobromic acid for headache; 69 were more or less delirious; 51 patients ate whatever they pleased—three of them relapsed, and seventeen had diarrhœa; 39 had restricted diet, and three relapsed.

Nearly all cases had in the beginning mercurial enough for alterative effect, and quinine to overcome any malarial element. All cases had tr. iodine, gtt. iij.; acid. carbolic., gtt. j.; sol. Fowleri, gtt. iij.; every six hours, unless not tolerated by the stomach; children had diminished doses.

I think (without any special notes) that cases treated with quinine, digitalis, and cold baths got through the disease less debilitated than those treated with salicylate of soda. I have found but little difficulty in keeping the temperature below 103° with antipyrine, salicylate of soda, or quinine, or all three in succession, if required. I now seldom resort to cold baths, but employ frequent spongings.

My patients have nearly all been among the well-to-do class, where everything in the shape of nursing, care, diet, ventilation, etc., desired was obtained.

W. H. FITCH, A.M., M.D.

ROCKFORD, ILL., August 28, 1887.

OUR LONDON LETTER.

(From our Special Correspondent.)

SODIUM FLUOSILICATE AS AN ANTISEPTIC AGENT—PROFESSIONAL ADVERTISING—SIR MORELL MACKENZIE AND HIS FEE—THE HOSPITAL SATURDAY FUND—THE THERAPEUTICAL SOCIETY.

LONDON, September 9, 1887.

NEW antiseptics are now so constantly brought forward that the announcement of yet another fresh one does not excite much comment. Yet if the last acquisition to the list but prove as valuable as its discoverer expects, it will bid fair to take a front seat among these substances.

The body in question is sodium fluosilicate, and it has been introduced to public notice by Mr. W. Thomson, who read a paper on it two days ago in the Chemical Section at the annual meeting of the British Association for the Advancement of Science. Sodium fluosilicate is stated to be not poisonous, to possess no smell, to be sparingly soluble in water, not volatile, and not to be destroyed by oxidation. As it has only a very slight saline taste, it has been suggested that it may be usefully employed for the preservation of food. It has already been tried for surgical purposes, and it has been found that a saturated solution (containing 0.61 per cent.) does not irritate wounds, while possessing greater antiseptic power than a solution of corrosive sublimate containing one part in a thousand. Fluorspar is the source whence the new antiseptic is to be prepared, and the supply of this is ample. As a secondary purpose it has been suggested that the new salt may be of value in sewage irrigation. Its discoverer has shown that it does not destroy grass so rapidly as common salt; so no injurious effects on vegetation are to be feared if it is employed for the purpose suggested.

It is rumored that Dr. Mackenzie received a fee equal to ten thousand dollars for his two trips to Germany to operate on the future emperor. He will probably receive an additional honorarium on concluding his attendance. But this is as nothing to the fees his royal patient will bring him indirectly.

It is announced in the *Court Circular* that Dr. Mackenzie arrived at Balmoral Castle the day before yesterday, and received the honor of knighthood "in recognition of his valuable services to the queen's son-in-law, the Crown Prince of Germany." Sir Morell Mackenzie cannot feel otherwise than satisfied with the phenomenal success he has achieved.

It is estimated that the Hospital Saturday Fund for the present year will amount to about twenty-eight thousand dollars. The Hospital Saturday Fund differs essentially from the Hospital Sunday Fund. The latter is chiefly the result of collections made in various places of worship on a given day (Hospital Sunday). It represents not so much the active sympathies of the various congregations with hospital work as the amount of money which can be raised by judiciously made collections. Probably as much could be raised for any other cause by the same agencies. The Saturday Fund was originally a workmen's fund, and consisted of collections made in various workshops and places of business. Of late years collections in the streets have also been made, and have helped materially to augment the receipts.

A new society has been started, yclept "The Therapeutical." It is as yet hardly well on its legs, but promises well. Some doubts were at first expressed that it might prove to be a quasi-homœopathic gathering, but I believe these have been dispelled satisfactorily. Dr. Sydney Ringer, F.R.S., is announced as the first president.

The Following Formulæ for the Relief of Asthma are given by correspondents of the *British Medical Journal:* 1. Take of daturæ tatulæ, stramonii, cannabis indicæ, lobeliæ inflatæ, āā ʒ ij.; mix with potassii nit. pulv., ʒ ij., and ol. eucalypti, ʒ ss.; burn a teaspoonful in bedroom, and repeat if necessary. (Put on white paper in a saucer it burns well.) Of course, the patient must observe rules of diet, going to bed on an empty stomach, lying with the chest raised, keeping the feet warm, and such like, without which few remedies will be of any avail. 2. Foliæ stramonii, ʒ iv.; foliæ lobeliæ, foliæ belladonnæ, āā ʒ j., to be thoroughly ground in a mill; potassi nitratis, ʒ ij.; tinct. opii, ʒ ij. Dissolve the saltpetre in the smallest possible quantity of hot water, and add the tincture of opium. Thoroughly saturate the mixed and ground leaves with this solution, and dry at a gentle heat. When dry mix well with thoroughly pulverized camphor, and preserve in a stoppered bottle.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 18 to September 24, 1887.

Cabell, Julian M., First Lieutenant and Assistant Surgeon. Relieved from duty in connection with the Annual Department Rifle Competition at Bellevue Rifle Range, Neb. Ordered for duty as Medical Officer at the "Rifle Camp for Team of Distinguished Marksmen," Bellevue Rifle Range. S. O. 89, Department of the Platte, September 10, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending September 24, 1887.

Harvey, H. P., Surgeon. Ordered to U. S. S. Mohican.

Cooke, G. A., Surgeon. Detached from the Mohican and ordered home.

Cleborne, C. J., Medical Inspector. Promoted to Medical Director, September 18, 1887.

Walton, T. C., Surgeon. Promoted to Medical Inspector, September 18, 1887.

Boyd, J. C., Passed Assistant Surgeon. Promoted to Surgeon, September 18, 1887.

Tryon, J. R., Surgeon. Ordered to Marine Rendezvous, New York, October 1, 1887.

Field, J. G., Assistant Surgeon. Detached from Marine Rendezvous, New York, and ordered to the Vermont.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 24, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	49	15
Scarlet fever	25	4
Cerebro-spinal meningitis	5	1
Measles	9	2
Diphtheria	88	31
Small-pox	5	0
Yellow fever	0	0
Cholera	0	0

Dioxide of Hydrogen.—Dr. J. Mount Bleyer, of New York, writes: "In a recent issue of The Medical Record, among the 'Medical Items,' I find reference made by Thomas Latham concerning the dioxide of hydrogen. He found the difficulty of obtaining and keeping a solution of a constant strength for any length of time. I must call his attention to the fact that I have kept some of Charles Marchand's C. P. Dioxide of Hydrogen in my office uncorked, and simply covered with a bladder-skin, pin-holed, for over six months without any appreciable change. The temperature was constantly kept below 65° F."

Dr. Martin on Tubal Disease.—In the course of the past five years Dr. Martin, of Berlin, has collected material for the study of disease of the Fallopian tubes from 287 cases, and a valuable paper recording his researches has been published in the *Zeitschrift für Geburtshülfe*, vol. xiii., part 2. Only 9 of these cases were under twenty years of age; the majority were in the most active period of sexual life; 220 were married;

113 had never borne children; as many as 61 had aborted once or oftener. Almost without exception there were other diseases of the pelvic organs, especially endometritis or pelvic peritonitis. In 147 cases the sources of the disease were chronic or acute affections of the endometrium; in 70, puerperal complications; in 55, gonorrhœa; in 3, recent syphilitic infection; and in 10, tubercle. In no case could Dr. Martin find evidence that the disease spread from the pelvic peritoneum up the tubes, while in 11 he could distinctly trace the extension of the inflammation on to the peritoneum, from rupture in 2 out of 11, from escape of discharges out of the ostium in the remaining 9. The left tube was the most frequently affected, but bilateral disease was very common. Dr. Martin divided tubal inflammation into "salpingitis catarrhalis," or endosalpingitis, where there is small-celled infiltration into the mucous membrane; "salpingitis interstitialis," where the infiltration involves the muscular coat; and "salpingitis follicularis," where to the interstitial infiltration is added the formation of pouches on the surface of the mucous membrane, which gradually riddle the muscular coat. The epithelium is shed, but the pouches or follicles may retain their epithelial investment. Dr. Martin's clinical observations are in accordance with the recent experience of British authorities. He only found radical operations necessary in less than a fifth of his cases, in nearly half of which both tubes required removal.—*British Medical Journal.*

Toxic Properties of the Urine of Different Animals.—At a recent meeting of the Paris Biological Society, MM. Charrin and G. H. Roger made the following communication concerning the toxic properties of the urine of different animals, and the influence of fasting and of a milk-diet thereon: "The urine of rabbits is nine times as poisonous as that of human beings. In twenty-four hours a rabbit eliminates for each kilogramme of its weight enough poison to kill 4.184 kilogrammes. The salts of potassium, which are contained in rabbits' urine in the proportion of 75 to 80 per cent., account for these highly toxic properties. A guinea-pig secretes about 163 cubic centimetres of urine per kilogramme; this urine has a density of about 1,013, and contains 2.16 grains of urea. It causes death when injected into the veins in doses of 28 to 29 cubic centimetres per kilogramme. Of the toxic properties of guinea-pigs' urine, 71 to 80 per cent. is due to the salts of potassium which it contains. Dogs' urine is less poisonous; a dog secretes about 72 cubic centimetres of urine per kilogramme. This urine has a density of 1,030 to 1,031, and contains 4.36 grains of urea. A dog eliminates in twenty-four hours, for each kilogramme of its weight, enough poison to kill 3.317 kilogrammes. Of this poison, 71 per cent. is due to the presence of salts of potassium. In fasting, the toxic properties of urine are considerably diminished, and are about equal in guinea-pigs and rabbits. In twenty-four hours enough poison, per kilogramme, is eliminated to kill 1.7 kilogramme on the first day of inanition; on the second day enough poison is eliminated to kill 1.6 kilogramme, and on the third day about enough to kill 1.5 kilogramme. If the animals be submitted to a milk-diet, the toxic properties of the urine attain a fixed degree, which hardly varies, and is reduced to one-third or one-half of the normal degree. Alimentation has a considerable influence on the difference of the degree of toxicity of human urine. The utility of a milk-diet in affections accompanied by intoxication is universally recognized. M. Bouchard has shown alimentary substances to be the principal cause of intoxication of the organism. In disorders in which the excretory functions are impaired, as in pyrexia, and in slow intoxication, like uræmia, the introduction of toxic substances should be avoided; a milk-diet is, therefore, indicated in such cases." The experiments of MM. Charrin and Roger, in showing the influence of a milk-diet on the toxic properties of urine, have given further proof of its value.—Paris Cor. *British Medical Journal.*

Ziemssen's Two Chief Therapeutic Measures in Typhoid Fever.—The only drug to which we can ascribe a kind of specific action is calomel, perhaps on account of its entire or partial changé, by the chlorine of the sodium chloride in the intestinal juices, into corrosive sublimate. I give calomel in three doses of gram 0.5 in two hours, and then obtain a number of thin grass- or moss-green (calomel) stools and a considerable reduction of temperature, which often goes down to normal and lasts about twelve hours. These are the primary effects of calomel. The secondary effects of the drug consist in a modification of the intensity of the infectious condition, as Liebermeister has shown. Those cases which are early subjected to treatment by calomel generally run a somewhat milder course than those in which it is not used, or only used later; milder both in regard to the fever as well as in the local affection of the intestine. Next to calomel, baths deserve the greatest consideration. On his admission to the hospital, if his condition is not too bad, the patient receives a warm bath to cleanse the skin and remove possible parasites. Then the course of the temperature for twelve or twenty-four hours is determined by hourly measurements, best

others actual cautery and prolonged rest in bed, but all in vain. Of this case, Débove says: "I passed the jet of chloride of methyl over the entire painful surface, from the hip to the external malleolus. A minute later this patient, who until then could not put his foot to the ground, walked around the ward without limping," etc. Since then many trials have been made, and although occasional failures have been reported, the almost uniform success observed is astonishing. Thus, R. D. Santelli,[1] in 1884, collected thirty cases of sciatica treated by this means, all of which were relieved, and, with the exception of one, remained free from pain. Many of these cases were seen after two months, but no relapse had occurred.

Of these, Case I. was a sciatica of fifteen months' standing, accompanied by slight atrophy of the leg. A cure was accomplished in three days. The second case was one of fourteen years' duration, and was cured after two applications. Other severe cases were cured in from one to thirty-three applications.

Soon after Santelli's publication, Dr. Olive, of Nantes, collected four cases of sciatica thus treated, three of which were cured after a single application. At the meeting of the Société Médicale des Hôpitaux, held January 9, 1885, various gentlemen reported their experience as follows:

Rendu: A case of double symptomatic sciatica, ameliorated.

Bucquoy: Three cases of sciatica and one of trigeminal neuralgia treated. Of these one case of sciatica cured, and the other three cases ameliorated.

Sevestre: Old case of sciatica, of six months' duration; cured after several applications.

Legroux: Case of severe old sciatica, cured.

On February 27, 1885, Tenesson[2] read a paper before the same Society upon the use of the methyl for the relief of various forms of pain. He produced 37 observations, embracing 10 cases of sciatica and 27 other sources of pain (not all neuralgic). Of the sciaticas, 7 were cured at once. In the other cases the pain was

Mr. Tait says that the time spent in learning German was wasted. He says (*N. E. Med. Journal*): "A very eminent German surgeon once cross-examined me as to my own notions concerning my exceptional success in abdominal operations. I evaded the real answer as long as I could, but at last, driven into a corner, I replied that I paid a great deal of attention to the cleansing of my finger-nails. He looked at his own and turned away. I do not know if he was a wiser man, he certainly was an angrier one. I have had no more German visitors, and I am being continually attacked in German medical papers." —*American Lancet.*

Electricity in the Infliction of the Death Penalty.—Dr. J. Mount Bleyer, of this city, writes: "In my perusal of your editorial columns of July 23d there appeared a critical review on 'The Infliction of the Death Penalty,' by Park Benjamin. I claim priority to this investigation, and therefore refer you and your readers to the daily papers of May 3, 1887, and since that date to 'The Humboldt Scientific Library' on that subject, where the publication of my investigation will be found. Under the title of 'Capital Punishment by Electricity, Hypodermic Injection of Morphia, and the Consideration of Other Methods as a Substitute for the Hanging in the Execution of Criminals,' I delivered a demonstrated lecture on the lower animals, before a political body, of which some of them were commissioned by the State, on capital punishment, and soon thereafter a bill was passed before the Pennsylvania Legislature, whereby criminals condemned to death will be executed by electricity."

"Christian Science" and "Mind-Cure."—In speaking of the Rev. Dr. Buckley's recent article on this subject, the *Boston Medical and Surgical Journal* says: "It is rumored that Dr. Mackenzie received a fee equal to ten thousand dollars for his two trips to Germany to operate on the future emperor. He will probably receive an additional honorarium on concluding his attendance. But this is as nothing to the fees his royal patient will bring him indirectly.

It is announced in the *Court Circular* that Dr. Mackenzie arrived at Balmoral Castle the day before yesterday, and received the honor of knighthood "in recognition of his valuable services to the queen's son-in-law, the Crown Prince of Germany." Sir Morell Mackenzie cannot feel otherwise than satisfied with the phenomenal success he has achieved.

It is estimated that the Hospital Saturday Fund for the present year will amount to about twenty-eight thousand dollars. The Hospital Saturday Fund differs essentially from the Hospital Sunday Fund. The latter is chiefly the result of collections made in various places of worship on a given day (Hospital Sunday). It represents not so much the active sympathies of the various congregations with hospital work as the amount of money which can be raised by judiciously made collections. Probably as much could be raised for any other cause by the same agencies. The Saturday Fund was originally a workmen's fund, and consisted of collections made in various workshops and places of business. Of late years collections in the streets have also been made, and have helped materially to augment the receipts.

A new society has been started, yclept "The Therapeutical." It is as yet hardly well on its legs, but promises well. Some doubts were at first expressed that it might prove to be a quasi-homœopathic gathering, but I believe these have been dispelled satisfactorily. Dr. Sydney Ringer, F.R.S., is announced as the first president.

The Following Formulæ for the Relief of Asthma are given by correspondents of the *British Medical Journal:* 1. Take of daturæ tatulæ, stramonii, cannabis indicæ, lobeliæ inflatæ, āā ʒ ij.; mix with potassii nit. pulv., ʒ ij., and ol. eucalypti, ʒ ss.; burn a teaspoonful in bed-

The Price of Civilization.—In Dr. Fothergill's recent address on "The Modern Tendency of Disease" (*The Medical Press*, August 17, 1887), the following interesting remarks occur: "While so much brain-work is being demanded something must suffer. We know that in the very early embryo there are three layers. The outer layer, or epiblast, gives the nervous system and the sensitive skin; in other words, the means by which the organism is in communication with its surroundings. The inner layer, the hypoblast, supplies the glandular apparatus of organic life. The middle layer, or mesoblast, furnishes the locomotor apparatus—bones and muscles—and also the vascular system. The mesoblast supplies the nutritive material to the tissue-derivatives of the other layers. In the primitive child the supply to the outer and inner layer is equal. The demands of education upon the nervous system, and specially the brain, as 'the organ of the mind,' disturbs this natural balance. The nervous system requires more than its normal share and the other structures of the body suffer accordingly, and in consequence. The viscera are smaller; the locomotor apparatus is dwarfed. There is disproportion. The brain-culture is impairing the physique. Town populations are bodily smaller than rural populations. The physique is deteriorated. The dentist can bear testimony to the inferiority of modern teeth. The oculist can tell of the increasing demand for spectacles among the young of our day. The human body is paying a price for the advantages of civilization. 'The modern struggle for existence is,' as Sir J. Crichton Browne, M.D., happily puts it, 'no longer fought with thews and sinews, but by the brain.' The brightest brain is the great matter of life to-day. If all this is true in the case of men, how stands it with women in the life of to-day? Instead of growing up a healthy domesticated creature, learned in all matters of the household, taught to ride and hawk and hunt, to be, indeed, the companion of the countryman of rustic ways and little culture, she now is sent to school at tender age; for she is destined to be educated and accomplished! School-life goes on alongside growth, with the same results in the girl as in the boy. But when puberty comes, a new demand is established upon the nutritive powers of the organism. The reproductive organs are derived from the Wolffian body of the mesoblast. In childhood they remain infantile; at puberty the female reproductive organs not only undergo development, but the monthly demand of the menses is superadded to the taxation of the nutritive powers. One of two things must give way. The catamenia are spoken of as 'a surplus wave of nutrition;' and how can a hardly taxed organism afford any surplus wave of nutrition? In the town girl we find frequently that puberty is imperfect. The external generative organs may undergo the adult transformation, but the uterus and its appendages remain infantile. It is no matter of fashion or caprice that so many girls at the present day prefer to earn their own living. They are practically sexless. They have no physiological aspirations to gratify, no ambition to become wife and mother. They contrast with the large-limbed women for whom motherhood is the true station in life. Betwixt the well-grown mother of heroes of the past, and the small, sexless spinster of to-day, there are a myriad blends, combinations, or varieties. The slight, neurotic town girl, bright and attractive, becomes a wife. With what consequences? Perhaps the gynecologist could enlighten us. In rural districts, and especially with women who are much out of doors, working in the fields, female troubles are all but unknown—the reproductive organs are fully developed. They may even be subjected to considerable rough usage with impunity and without injury. Not so the town product. With her, physical exercise has been limited in order to enable her education to proceed. The pelvic muscles are imperfectly developed, and the uterus lacks the usual support. When the reproductive organs are called into play on marriage they reveal their imperfection. The woman with an infantile uterus and ovaries remains sterile and unimpregnated; because she is not capable of impregnation. The highly susceptible nervous system may be an incitement to sexual indulgence in those so inclined, but the undeveloped organs give way under the calls of spousal duty. These are the organisms which are to the gynecologist the very breath of his nostrils. It is their exigencies, indeed, which have called him into being. Thus we see that women as well as men pay a price for civilization."

THE TREATMENT OF NEURALGIAS BY MEANS OF INTENSE COLD.[1]

BY GEORGE W. JACOBY, M.D.,

PHYSICIAN TO THE CLASS FOR NERVOUS DISEASES OF THE GERMAN DISPENSARY OF THE CITY OF NEW YORK.

THE subject of this paper is not by any means new; cold has been used in the treatment of neuralgias since time immemorial, and many of the good results attained are to be ascribed to this means. We have all made use of ice-applications; some of us have used the various ethers, applied in a spray form by means of a Richardson atomizer; and the menthol cone, whose action is due to the cold produced by evaporation, is also familiar. However, since 1884 our methods of applying cold therapeutically have been, so to say, revolutionized, and this has been accomplished by the introduction of chloride of methyl into our therapeutic armamentarium. Since Débove recommended this agent for the treatment of sciaticas, reports of so many successes with its use have been received from other quarters that we simply cannot avoid paying some attention to the matter. Since Débove's first publication I have, at different times, given considerable attention to the therapeutic action of the various refrigerants, and have finally come to the conclusion that we possess only two which can be easily and practically utilized. These are the chloride of methyl and the fluid carbonic acid, and it is to the employment of these agents that I shall limit my remarks to-day.

Chloride of methyl was discovered in 1834, by Dumas and Peligot, and was produced by them by heating a mixture of sea-salt, methylic alcohol, and sulphuric acid. This process, however, was complicated and expensive, and only of late years has it been obtainable in a pure state and sufficiently cheap to be utilized. This is due to a new process invented by C. Vincent. All the chloride of methyl now used in France is manufactured near Paris, under his special patents, and is used in commerce principally for the extraction of perfumes. His process consists in submitting to the action of heat the chlorate of tri-methylamine, which is obtained from the remnants of beets used in the manufacture of sugar.

The chloride of methyl itself is, at ordinary temperature, a colorless gas of etherous odor and sweetish taste, boiling at 23° Cent. Below that temperature it can be kept in a liquid state only by enclosing it in very strong recipients, in which its tension becomes higher in direct proportion to the external temperature. If now it is allowed to escape into the air it at once returns to the gaseous state, and this return is accomplished only by means of a reduction of temperature to —23° Cent., and even under some circumstances as low as —40° Cent. This is the principle of artificial refrigeration as it has been employed for years by Malassez and Ranvier for congealing histological specimens. As stated, the first therapeutic application of this substance was made by Débove,[2] and the train of thought which led to its employment was as follows: He argued that some of our best successes obtained in the treatment of sciaticas were due to counter-irritation; but that all the counter-irritants thus far employed acted only upon a limited number of nerve-filaments, and that, therefore, congelation of the skin, accomplished in such a manner as to allow of its return to its normal condition, would be the means of producing very extended counter-irritation. After repeated trials, he concluded that this object would be accomplished by the use of the methyl.

The first patient thus treated was one affected with sciatica. Various remedies had been applied, among others actual cautery and prolonged rest in bed, but all in vain. Of this case, Débove says: "I passed the jet of chloride of methyl over the entire painful surface, from the hip to the external malleolus. A minute later this patient, who until then could not put his foot to the ground, walked around the ward without limping," etc. Since then many trials have been made, and although occasional failures have been reported, the almost uniform success observed is astonishing. Thus, R. D. Santelli,[1] in 1884, collected thirty cases of sciatica treated by this means, all of which were relieved, and, with the exception of one, remained free from pain. Many of these cases were seen after two months, but no relapse had occurred.

Of these, Case I. was a sciatica of fifteen months' standing, accompanied by slight atrophy of the leg. A cure was accomplished in three days. The second case was one of fourteen years' duration, and was cured after two applications. Other severe cases were cured in from one to thirty-three applications.

Soon after Santelli's publication, Dr. Olive, of Nantes, collected four cases of sciatica thus treated, three of which were cured after a single application. At the meeting of the Société Médicale des Hôpitaux, held January 9, 1885, various gentlemen reported their experience as follows:

Rendu: A case of double symptomatic sciatica, ameliorated.

Bucquoy: Three cases of sciatica and one of trigeminal neuralgia treated. Of these one case of sciatica cured, and the other three cases ameliorated.

Sevestre: Old case of sciatica, of six months' duration; cured after several applications.

Legroux: Case of severe old sciatica, cured.

On February 27, 1885, Tenesson[2] read a paper before the same Society upon the use of the methyl for the relief of various forms of pain. He produced 37 observations, embracing 10 cases of sciatica and 27 other sources of pain (not all neuralgic). Of the sciaticas, 7 were cured at once. In the other cases the pain was relieved.

F. Rouillon,[3] in his thesis, adduces 25 cases of sciatica thus treated; 4 cases of hyperæsthesia, 3 of which are cited from the *Progrès Médical*, May 9, 1885, one of these of very great severity and long duration, all cured after one application; also 6 cases of intercostal neuralgia cured or relieved after one or more applications; furthermore, 5 cases of trigeminal neuralgia, 4 of which were cured and 1 relieved.

The duration of these last cases had been from three

months to fifteen years, and in two both nerve-stretching and resection had been performed without success.

Finally, A. Peyronnet de Lafonvielle[1] adduces 8 cases of trigeminal neuralgia which had existed for a long period of time, and which were all relieved after several applications.

It has always appeared to me that statistics of this kind should be received with a certain reserve, and that they are to be considered as only of relative value. My reasons for this view are that cases of failure are in many instances left to go unrecorded; that for the effect produced upon the pain we must take the patient's own statement, and it is well known that patients often exaggerate the pain in the first place, and the influence of any new mode of procedure in the second.

Finally, cases are often reported as cured which, if observed for a sufficient length of time, would prove not to be at all benefited. Nevertheless, when we are confronted by such an array of facts as are presented here, we cannot well avoid attaching some importance to them.

In the first successful experiments the substance was contained in a thick glass siphon, similar to those used for carbonated waters, and was provided at the top with an attachment-piece which enabled the production of a fine jet. Previously a Richardson atomizer had been employed, but with entire failure. Even the use of the glass siphons proved unsatisfactory, for several explosions occurred, and consequently their abandonment became imperative. Finally, an apparatus of metal was constructed, which, being sufficiently strong to withstand the great pressure, at the same time was easily transportable and of comparatively easy manipulation. This is the apparatus which I now have the honor of showing you. As you see, it consists of a copper cylinder, the capacity of which is about one litre. The upper part is furnished with a strong screw, which, when fastened down, admits of no escape. When unscrewed the fluid escapes through a lateral opening, to which is attached a metallic regulating apparatus furnished with a micrometer screw, and which admits of delicate regulation of the spray. The method of application is as follows: The screw at the top is opened after having ascertained that the screw of the regulating apparatus is closed. The opening of the atomizer is then directed obliquely against the part to be treated, and then set into action by loosening the micrometer screw. The jet is then moved over the entire course of the nerve, also being applied to the surrounding parts. During the entire application the cylinder must be held in the left hand, and the right one must not be removed from the regulating apparatus.

The length of time during which it is admissible to act upon one spot cannot be estimated in seconds, but will depend upon the coloration which the skin assumes. As soon as it grows very pale the jet must be displaced. This occurs in a few seconds, but will vary in different places, according to the thickness or thinness of the skin. The skin must be continually under observation, and the apparatus displaced at the proper time. There is absolutely no difficulty in this, but continuous attention is necessary. As the skin becomes pale it also becomes hard, and the patient complains of a burning feeling. As soon as the entire nerve has been acted upon in this manner the patient is generally free from pain. In the majority of cases the pain returns again, after a few minutes, at certain points. These must be at once treated again, and thereupon the pain will be entirely gone.

Relief after the first application is the rule, but sometimes a second one is necessary. As stated, the spray must be directed obliquely against the skin, and not vertically, for in the latter case the great pressure produces a depression of the tissues, and this depression is the frequent seat of a blister or an eschar. A large surface must also be acted upon, as the success is to a great extent dependent upon this. Sluggishness of circulation, with reduced vitality of the skin, would contraindicate its use. There are certain objections to its use, which, however, are only of relative importance.

The pain produced by the application is rather severe, but it is never as great as that produced by the actual cautery or the galvanic brush.

Hyperæsthesia and redness of the skin remain in some cases for hours, and even for days.

Vesications and eschars may be produced if sufficient care is not taken in the application; but Débove, in 1885, said that he had then used it over a hundred times without producing an eschar. Pigmentation of the skin occurs occasionally, but this passes away after several weeks at the utmost.

Finally, there is one objection to its extended use here, and this is at present the most important of all; I refer to the high cost of the apparatus, and the difficulty of getting it refilled. The cost of the apparatus delivered here in New York is $37.50, and each vessel contains only sufficient of the chloride for four applications to an entire limb, as in a case of sciatica. When empty, the vessel must be sent back for refilling, and although the cost of refilling in Paris is only six francs, the trouble of sending the apparatus over, the time lost in awaiting its return, the possibility of a cylinder arriving minus its contents, and, finally, the difficulty of getting the steamship companies to carry it at all, on account of the supposed danger of explosion, all render its extended use at present almost impossible. Should, however, a sufficiently large demand for it arise, Messrs. Eimer & Amend, of New York, say that it could be manufactured here. On account of this difficulty in obtaining it, I made use of it only for the treatment of trigeminal neuralgias, in which the amount used is necessarily very small. I have thus treated five cases in all—three fresh ones, of from one to five weeks' standing, and two old ones, the one of six months' and the other of two years' duration. There is no necessity for entering upon details of the cases themselves. In all five cases the pain was entirely relieved after the first application. In one of the fresh cases there was no return of the pain. In the two others the pain returned, and a second application was made, with the result of relieving the pain again. In these also there has been no return. One of the old cases was so much ameliorated after four applications that he discontinued treatment, although not entirely well. In the fifth case I was able only to obtain relief from pain after each application, and although six applications were made, there is no sign of permanent improvement.

My general impression from this brief experience is, that *we have in the chloride of methyl a reliable analgesic, which does not affect the general condition of the patient, and that it is invaluable in the treatment of neuralgias for the immediate relief of severe pain.* On account of the difficulty of obtaining the chloride of methyl, I made use of the condensed carbonic acid for the treatment of the cases of sciatica which came under my observation. I was led to the use of this gas by the following considerations:

Firstly, as far back as 1835, Dr. Dewees, of Philadelphia, used it as a local anæsthetic, and this observation was subsequently corroborated by Major, of Geneva; Pereira, James Y. Simpson,[1] Demmé, and Scanzoni.

Demmé[2] showed that this gas, as such, without any reference to its refrigerant qualities, possessed anæsthetic properties. In this article he says: "Upon immersing the arm (in this gas) no effect was for several minutes perceptible, then a slight pricking could be felt or imagined, which soon, however, gave way to a sense of numbness in the hand. The skin of the hand

and arm, after being immersed in the gas for about ten minutes, could be violently pinched without causing pain."

Secondly, because of its non-irritating properties.

Thirdly, on account of the great pressure necessary to keep it fluid. Knowing that six hundred pounds of pressure to the square inch are necessary to keep it fluid, whereas the chloride of methyl requires only sixty, I thought that in the liberation I would obtain also a proportionately greater amount of cold.

Finally, the condensed carbonic acid is very cheap, and in metallic cylinders containing ten pounds and more forms a staple article of commerce. I made use of one of these cylinders, and adapted it to my purpose by attaching a long tube of lead to the escape-vent, in order to a certain extent to reduce the rapidity of the evaporation. At the free end of this tube I attached the same arrangement for regulating the spray as is employed with the chloride of methyl apparatus.

My first trials were decidedly unsatisfactory. The objections to its use were found to lie in the heaviness and non-volatility of the fluid gas, and that in consequence its action was confined to a comparatively small surface, the spray produced being very concentrated and not spread out as the chloride of methyl spray. So also the great pressure with which the gas is liberated causes a great depression of the tissues at the point where the gas strikes, and that in consequence of this an eschar was produced at this point.

These objections were finally overcome by allowing the spray to first strike the surface of a piece of curved sheet-tin, and from this it is deflected against the limb. In this manner the spray is spread out, its force broken, and the eschars are avoided. There are still, however, several changes necessary if the cylinder is destined to be used. Firstly, it must be made smaller and more portable; and secondly, a narrow tube must be run inside of the cylinder almost to the bottom, so as to enable fluid to be drawn in the vertical as well as in the horizontal position. At present fluid can be obtained only in the horizontal position; if the cylinder is placed upright gas alone is obtained. These changes will be made by Eimer & Amend, should there be any demand for the gas for therapeutic use.

In all, I have by this means treated ten cases of sciatica, not counting the first experimental cases, and have made about fifty applications. Only once did I produce an eschar, and this was not of any severity. The pain was generally entirely relieved after the first application, but in some cases another and more extended application was requisite. In two of these cases the pain had not again returned after four weeks. In the other cases the pain returned again in from three to twenty-four hours, although not always with the same intensity. After several applications five of these cases were so much relieved that they could attend to their business, although they were not entirely well. Finally, in three cases there was no result at all, beyond the relief from pain after each application.

In short, my conclusions are that the carbonic acid, used as above stated, is, in the absence of the chloride of methyl, able to take its place in the treatment of sciatica. That the pain is relieved very promptly by its use, but that its curative effect is not as great as that attributed to the chloride of methyl by other observers. Repeated and extended trials alone can demonstrate its utility or worthlessness in this regard. If even these future observations should show that in intense cold we possess a remedy which is capable only of *relieving* pain, we still will have very valuable remedies in the chloride of methyl and carbonic acid, remedies which all of us, who have at times found it almost impossible to relieve the intense sufferings of some of our patients, will know how to appreciate. In conclusion, I desire to make a few remarks as to the *modus operandi* of these substances in the relief and cure of pain.

It is not at all probable that either of the substances employed exerts its action through any inherent virtue. The length of time that they remain in contact with the skin is so short that even if they possessed any such virtue the time would be insufficient for their absorption—consequently the action can be attributed only to the intense cold produced, and the majority of observers look upon it in this light, believing that the cold acts as an anæsthetic upon the terminal expansion of the sensitive nerves. In addition to this action the same effect is produced as by the use of any counter-irritant. Thus the temporary relief of pain is easily understood, but why in many cases there is no return of the pain has not been satisfactorily elucidated.

Ever since reading the "Bradshaw Lecture" for 1883, by John Marshall,[1] I have come to agree with this author that in very many cases the neuralgic pain is situated in the nervi nervorum. At that time the existence of these nerves was only surmised by Marshall, but since then Mr. Victor Horsely has satisfactorily proven their existence.

In a paper read before the Royal Medical and Chirurgical Society of London, January 22, 1884, on the existence of sensory nerves in nerve-trunks, Horsely showed that besides the vaso-motor nerves of the vessels of the epineurium, as described by Sappey[2] and Krause,[3] there existed also true sensory nerves concealed by the fat-globules of the epineurium and terminating by end-bulbs on the epineurium. These nerves appear to arise occasionally from the primary bundles of nerve-fibres, but also from the terminal branches given off by these. Their direction is first at right angles to the primary bundles, and then parallel, running as single medullated fibres of medium size in the connective tissue of the epineurium, and terminating in end-bulbs which consist of a connective-tissue capsule and protoplasmic core, close around which the axis-cylinder can be traced. Now admitting, as we must, the existence of these nerves, we can easily understand that they must be acted upon much more intensely by the severe cold than the underlying nerve-fibre itself, and that in many instances they are entirely destroyed, or, at any rate, completely paralyzed.

Thus I account for the cases of permanent cure, which of necessity must also be a rapid one. Certainly I am far from believing that the pain in all cases of neuralgia is in the nervi nervorum, and consequently in those cases in which the seat of pain is in the nerve-fibre itself, this seat not being so accessible to the freezing process, the pain will necessarily return after a longer or shorter interval.

THE EXPULSION OF THE PLACENTA.—Opinion among obstetricians is now pretty well divided into two views concerning the removal of the placenta after labor. The method of expectancy has been pretty well discarded, and there are probably few obstetricians who do not remove the placenta either by traction or expression, or by the two methods combined. Each of these two methods possesses advantages which are clearly understood by most obstetricians; still, it is not uncommon to find partisans who hold to the practice of one method in all cases to the exclusion of the other. To such men we present to their consideration the very concise statement recently made by Dr. A. Auvard, of Paris, who says: "Do nothing during the first period of the third stage when the placenta is separating; interfere, if need be, during the second period by expression through one hand on the uterus and by traction on the cord with the other hand; during the third period keep up traction with the one hand and steady the uterus with the other." Dr. Auvard refers of course to the purely normal stage. In cases of complication the management must differ according to the conditions observed.—*Maryland Medical Journal*, July 30, 1887.

TEREBENE IN DISEASES OF THE LUNGS.[1]

By D. M. CAMMANN, M.D.,

NEW YORK.

Terebene is the result of the action of sulphuric acid upon oil of turpentine. It becomes bland and oily by keeping, and in this condition is best for medicinal purposes. It is clear, colorless, and does not mix with water. Like turpentine, it imparts to the urine a distinct odor of violets. Terebene was first brought into notice, in a short article,[2] by Dr. Murrell, of London. He does not give histories of his cases, and they apparently include chronic bronchitis, emphysema, and phthisis, as well as others that were acute. He reports favorable results in all his cases—one hundred and fourteen in number. In a subsequent notice of cases occurring in the practice of other physicians, and reported [3] by him, the results were not quite so favorable. Dr. Suckling [4] has reported on the use of terebene in cases of chronic bronchitis and chronic phthisis. Seventy-two per cent. of his cases were relieved, and twenty-eight per cent. were not relieved. Many of his patients complained of nausea, of headache, or of thirst; two were troubled with vertigo, one with burning sensations in the stomach, one with frequent micturition, and two were purged.

During the past year I have used terebene frequently, and careful histories of a number of the cases have been kept by Dr. W. L. Carr. They include cases of emphysema, bronchitis, and phthisis. A few histories will be given in full, and a synopsis of the results in the other cases.

Case I. *Emphysema accompanied by bronchitis and pleuritic adhesions.*—M. N——, aged seventy, a sailor; November 4, 1886. No history of lung trouble in the family.

Previous history: Has had trouble with chest since boyhood; been short of breath since he was fifteen years of age; he did not have any cough until fifteen years ago, when it began in the winter-time. It generally came on at night, when he was lying down; seldom in daytime. Expectoration has been difficult; sputa whitish, never much; never any blood in expectoration. Never any fever nor night-sweats.

Present history: He is short of breath on exertion, and on lying down, also in damp, foggy weather; coughs, but most at night. Expectoration is difficult, never much at a time, and white. No night-sweats. Appetite fair. Bowels regular.

Physical examination: Slight bulging over upper part of chest; increased pulmonary resonance; respiration feeble; expiration prolonged; sibilant râles on forced respiration; a few coarse, dry râles at bases of both lungs posteriorly and right interscapular region; vocal fremitus and resonance increased over right side behind. Accentuated pulmonary second sound.

Treatment: Terebene, gtt. x., q.i.d., and cod-liver oil.

November 16th.—Does not cough as much; expectoration easier; sputa thinnish and more watery; breathes easier. Appetite good. Bowels regular. Urine same.

December 4th.—Coughs very little, only at night: respiration easy; expectorates hardly anything.

December 11th.—Continues to improve.

January 22, 1887.—Coughs very little, generally at night; respiration easy. Appetite good. Treatment continued.

February 5th.—Respiration not quite as easy for past two or three days. Cough a little hard for some time. Thinks that he caught cold. Increased frequency of urination. Bowels regular. Appetite good. Increased terebene to gtt. xv.

March 1st.—Very little cough. Expectoration white. No pain. Bowels regular. Urine free; passes it once or twice at night.

June 11th.—Coughs a little at night; not at all during the day. Only short of breath when going up-stairs. Has not required any terebene for the past two months.

Case II. *Asthma.*—J. M——, aged twelve; November 20, 1886. His mother had asthma. He first had asthma in his sixth year. It would come and go; had also a dry cough. Last year he was almost entirely free from it. Has lost in flesh; has night-sweats; no hæmoptysis. Now he is short of breath at night when lying down, on exertion, and on exposure to dust or wind. He coughs day and night; expectoration difficult, yellowish or white, and in large quantity. Appetite fair. Bowels regular.

Physical examination: Increased pulmonary resonance over front of chest; prolonged expiration over both lungs, and sonorous and sibilant râles varying in pitch; puerile respiration. ℞. Terebene, gtt. v., q.i.d. Cod-liver oil and the compound syrup of the hypophosphites were also prescribed.

November 30th.—Respiration easy; not coughing as much; expectoration whitish. Bowels costive.

December 7th.—Slight dry cough; no expectoration. Bowels open once a day. Urine same.

December 23d.—Not much cough. Treatment continued.

January 8, 1887.—Coughs a little in the day; no expectoration; not short of breath at any time, except on severe exertion. Sleeps well. Perspires easily. Appetite good. Bowels regular. Urine same.

Physical examination same as last time, except no sibilant or sonorous râles. Few coarse râles at left base posteriorly.

January 29th.—Cough loose; expectoration hard and yellow; some wheezing at night.

Case III. *Emphysema with bronchitis and pleuritic adhesions.*—D. H——, aged forty-one, engineer; December 9, 1886. His mother died of heart disease; family history otherwise good. Used to be a drinker. Had gonorrhœa thirteen years ago; "chancres" about the same time. They were burnt out and he had no after-trouble. Has had bad cough since February, 1886, with pain on the right side of the chest; would cough most at night and early in the morning on rising. Expectoration difficult; sputa yellowish and thick. Was sometimes short of breath and generally so when first in bed. He could not rest on right side or back, as in either position dyspnœa and cough would be increased. Night-sweats very severe.

In December, 1885, had hæmoptysis, and lost considerable blood. Since then has had four hemorrhages. Occasionally the sputa have been streaked with blood. Weight, formerly, 164 pounds.

Present condition: Coughs most in the morning and at night; expectoration free; sputa generally yellow, sometimes white, always thick. Cannot rest on right side or on back. Has dyspnœa on severe exertion; not much when lying down. No night-sweats nor fever. Appetite good. Bowels open every day. Weight, 130 pounds.

Physical examination: Depression above and below clavicles. Slight bulging over cardiac region. Dulness in right infraclavicular and suprascapular regions and left infrascapular region. Increase of pulmonary resonance over other regions; harsh respiration over both lungs, most marked under right clavicle; in right infraclavicular region and over anterior border of lung inspiration shortened, and expiration a good deal prolonged; expiration a little longer than inspiration over both lungs; a few subcrepitant râles in left infrascapular region. Heart-sounds feeble.

Treatment: Terebene, gtt. x., q.i.d.

December 14th.—Cough bad. Expectoration difficult; sputa yellowish; no blood. Bowels open once a day. Urine about the same. Says that he vomits sometimes

[4] Suckling: Pure Terebene in the Treatment of Winter Cough, British Medical Journal, March 20, 1886.

after eating; has feeling of rawness over chest. Short of breath. Thinks that he has caught fresh cold. Increased terebene to gtt. xv., q.i.d.

December 23d.—Feeling better. Sputa whitish. Bowels regular.

January 6, 1887.—Coughs most in the morning. Expectoration easy; sputa yellowish, and not as much as formerly; respiration about the same. "Rawness" over chest. Appetite good. Bowels not always regular.

Physical examination: Increased pulmonary resonance over both lungs in front. Over both lungs, in front and behind, inspiration shortened (least marked in infrascapular regions); expiration prolonged; respiration harsh; a few coarse râles over both lungs in front; coarse râles most abundant and intense in right scapular region.

January 13th.—Has considerable trouble with stomach; vomits about half an hour after meals, and then only when coughing. No difficulty after taking medicine. Passes urine more frequently during the day, but not at night. Sleeps well at night. Drinks a great deal of milk.

January 27th.—Coughing more during the day. Coughs some at night, but rests pretty well. Feels worse on rainy, damp days. Breathing still short. Stomach much better.

February 8th.—Coughing a great deal. Fits of coughing at night. Will only rest for two or three hours. Feels "stopped up" in the morning. Rawness over the chest. Dyspnœa about the same. Easily exhausted. Stomach in not very good condition. Has been out of terebene for past two days, and thinks that his stomach has been in better condition since then.

Case IV. *Bronchitis and pleurisy.*—L. W——, aged thirty-three, painter; December 18, 1886. His family history is good. He has been a painter for thirteen years. Two years ago he had chancres and gonorrhœa; three years ago dysentery. Had painters' colic seven years ago; has not had an attack since. Had slight cough three years ago, but no expectoration, dyspnœa, nor night-sweats at that time. One month ago had a cough and tickling sensation over the sternum, and some pain in left infrascapular region. Coughed when lying down; no expectoration except in the morning; sputa white. No dyspnœa. Now he has paroxysms of coughing once or twice during the day. He has lost in weight. Bowels regular.

Treatment: Terebene, gtt. xv., q.i.d.

Physical examination: Dulness on percussion from second rib to base of right lung in front. Harsh respiration over both lungs. Crepitant râles in abundance at right base in front, and a few over left scapular region. Coarse râles in left infrascapular region.

December 21st.—Cough less; expectoration the same. Pain less. Urine not increased. The crepitant râles have disappeared. A few coarse râles heard where the crepitant râles were previously.

January 11th.—Does not cough at all. No dyspnœa. Bowels regular.

Case V. *Phthisis pulmonalis.*—E. B——, aged thirty-six, fireman; December 23, 1886. Family history is good. Has been accustomed to drink more or less, but not much spirits. Has never had rheumatism or venereal disease. Is exposed to a great many changes in temperature. For the past eight or nine years has had more or less cough during the winter. Never had any pain. No bloody expectoration. Never had night-sweats. On the 27th of September he was in wet clothes for several hours. Since then has had cough, with whitish, frothy expectoration. He expectorates just before going to sleep, and in the morning. Has dyspnœa sometimes when lying down.

Present condition: Has cough, mostly in the morning; sputa generally frothy; not yellowish. Sometimes short of breath when coughing. Can sleep just as well in any position. No night-sweats. Does not feel as strong as he did. Appetite not as good as usual. Bowels move every day.

Physical examination: Right border of heart one inch to right of sternum at third rib; apex-beat just within line let fall from nipple; apex-beat diffused; first sound at apex prolonged and muffled. On percussion, slight dulness at right apex of lung in front; increased pulmonary resonance over both lungs in front; at right apex, in front and behind, bronchial breathing; over remainder of lungs respiration feeble, and expiration prolonged; coarse râles at right base in front and a few over the left lung behind. ℞. Terebene, gtt. xv., q.i.d.

December 28th—Cough much better. Coughs mostly in the morning, seldom at night; sputa whitish and thinner than formerly. Breathing very much easier. Sleeps all night. Bowels regular. Urine same. Appetite is pretty good.

March 31, 1887—Very much improved. Coughs only after a great exposure and when out of medicine. No pain. Appetite good. Bowels regular. Passes urine freely.

Case VI. *Acute bronchitis* in a child ten years of age. She had had cough two days previous to presenting herself for examination.

Physical examination discovered sibilant and coarse, moist râles scattered over the chest in front and behind; coarse, dry rales directly under the ear in the left infrascapular region. She was given terebene, ♏ v., in mixture, three times daily. The cough, dyspnœa, etc., passed away in a few days, and on examination, two weeks after first taking the medicine, the chest was found to be in a normal condition.

An analysis of the histories of eighteen cases shows that eight were emphysema, six bronchitis, three phthisis, and one asthma and bronchitis. Two cases of bronchitis, one of which had lasted for a few days, and the other for a month, were cured. Three cases of chronic bronchitis showed great improvement. One case showed no improvement after taking ten drops of terebene every four hours for five days. In this case the treatment was subsequently changed several times without any improvement occurring in the patient's condition. Seven of the cases of emphysema improved, and most of them to a marked degree. One case was unimproved after taking the medicine for two months. The three cases of phthisis and the case of asthma all improved. The time that the cases were treated varied from a few days to five months. The average length of treatment was fifty-five days. The terebene was given either dropped on sugar or in a mucilaginous mixture, in doses of from ten to fifteen minims, three or four times daily, and occasionally more frequently. In nearly every case the terebene was given without any other drug. Of these eighteen cases only two, or one in nine, were unimproved. In the other cases the dyspnœa was diminished, and usually to a marked degree. In fact, dyspnœa was the symptom upon which terebene seemed to have the most uniform and favorable results. The expectoration was thinner and lessened in quantity. In eight out of sixteen cases the patients said that the urine was increased; in the other eight cases they had noticed no change. In two cases vomiting occurred, but it was after eating or coughing, and the patients themselves did not attribute it to the medicine. In two cases hæmoptysis ceased a short time after taking the terebene. I regret that it has been possible for me to use it in only two cases of hemorrhage, as the result was so favorable as to warrant its further trial.

Terebene in some of its effects resembles turpentine, but is less irritating. In one case a patient took by mistake a teaspoonful every four hours for a week without any unfavorable result (Murrell). In none of my cases were the bowels affected. In those in which the urine was increased, no signs of extreme irritation followed, even when the drug was used for several months.

In addition to the cases already mentioned, I have

used terebene in forty or more cases in which histories have not been kept, but in which the results were equally favorable.

The cases reported in this paper are not, perhaps, a sufficient number from which to draw general conclusions, but taken in connection with those already reported it may be said that we have in terebene a valuable drug. It is useful in acute cases, and in chronic cases of emphysema it seems especially beneficial in relieving the dyspnœa.

THE INCREASE OF THE INSANE, AND SOME PROBLEMS CONNECTED WITH THEIR PUBLIC CARE.

By WILLIAM D. GRANGER, M.D.,

FIRST ASSISTANT PHYSICIAN, BUFFALO STATE ASYLUM FOR THE INSANE, BUFFALO, N. Y.

THERE is much talk about the rapid increase of insanity, and but little exact knowledge in the public mind regarding it. It is easy, from the records of this State, to show just what the visible increase is. What is true here is practically true of the whole country. By visible insane, I mean all who are in asylums.

From October 1, 1880, to October 1, 1886, there has been an increase of 4,001 insane persons in the various asylums in this State, or an average of 666 yearly. The increase for 1886 was 831. In 1870 there were 5,623 insane persons in our State, county, city, and private asylums; in 1880 there were 9,537, and in 1886 they had increased to 13,538. But a small part of these are supported at private expense; they are mostly a public charge. The same rate of increase would give 16,202 to be cared for in 1890, and 22,862 in 1900.

A little further study will show that the insane are increasing in a more rapid ratio than the population. In 1870 there was 1 insane person in the various asylums of the State to every 779 of the population; in 1880, 1 in every 532; and in 1886, 1 in every 406. This last is based upon an estimated population of 5,503,543, in accordance with the known increase from 1870 to 1880. Probably the population is some greater and the proportion a little too high.

While an increase of 666 insane, scattered over the State of New York, is easily assimilated, yet, continued year after year, it makes an increase difficult to care for, and a demand upon State, county, and city.

What a task the State has before it alone in caring for this class of its dependent citizens! It must yearly provide for over six hundred new, though by no means recent, cases of insanity. It is easy to illustrate what this means. The State Asylum at Utica has a capacity for six hundred patients. It reports the value of its buildings and farm to be $670,822. The yearly increase of the insane is greater than the capacity of the Utica Asylum, and if they are to be cared for as they are in that institution, it means an annual expenditure of over $700,000. And practically, unless the insane are to be improperly cared for, and crowded into the county and city asylums, this increase cannot be met by an expenditure of less than $500,000 a year. So that by the year 1900 the State, counties, and cities will be called upon to expend $7,000,000 for this object. Will they do it? Probably they will not, but they *must* do a large part of it.

It is easy to draw illustrations from the past upon which to calculate our future needs and expenses. In 1870 there was but one finished asylum in the State—that at Utica—while the Willard Asylum was just opening its doors. The value of asylum property was $1,725,908. In 1886 there were six asylums, and the value of their property was $5,876,725. It is impossible to estimate the increased value of city and county asylums, but it must be very large.

This large expenditure in the past by no means stops the present demand for more money and larger accommodations. Within two years the State has appropriated over $1,000,000 for buying land, building new asylums, or enlarging and improving its present institutions.

The asylum at Poughkeepsie has been increased by an added capacity for five hundred more patients. The asylums at Binghamton, Willard, and Middletown have been enlarged. The Buffalo asylum is authorized to enlarge for one hundred and fifty more patients The Legislature this year appropriated money for a criminal asylum to accommodate four hundred and fifty, and ordered to be bought at Ogdensburg nine hundred and fifty acres of land, and provided for a new asylum to be erected there. Within this time the county of New York has purchased one thousand acres of land upon which to build a new asylum; Kings County, seven hundred and fifty acres for the same purpose; Erie County has enlarged its buildings, and still sees before it the demand for a larger farm and increased accommodations; Monroe County has enlarged its capacity and hired land. And so, throughout the State, there is everywhere a constant demand for more money to build, more room in which to care for the insane.

It is not within the province of this paper to discuss the causes for this increase. It is a very complex and not well understood subject. There are, however, a few causes easily observed, aside from the increase of population.

1. The large number of foreigners coming into our State that are either insane or possess in themselves or their first generation all the essential elements to produce the disease.

2. The prolonged life of the chronic insane, due to their improved care in the many asylums of the State.

3. The improper and delayed treatment in too many of the county asylums, or in the homes of the insane, during the acute and curable stage.

4. The increase of asylums and their nearness to the people makes them more used.

Of the first cause there can be no reason to look for its limitation of action without efficient laws and active control by the General Government. There is a limit to the action of the second cause, and in the older countries, like England, it is thought to have been already reached. Nothing but strong legislative action, and a watchful Supervisory State Commission with ample powers, can control the third cause. While there are many notable exceptions, too many counties, from false ideas of economy, send their acute insane to their county asylums, or refuse to furnish public aid to send them to State institutions. The fourth cause is in active operation, and, by fixed laws, always exerts an influence in increasing the number of the insane supported at public charge.

It is safe to say that the number of our insane will increase until one in less than every four hundred of our population will be confined in our State, county, city, and private asylums.

It is very much to be regretted that the reports of our asylums do not furnish that information by which two very important questions can be answered. First, are the number of acute and curable cases of insanity increasing in a ratio greater than the increase of population, and to what extent do they add to the chronic class? And second, are those types of insanity which, from the beginning, belong to the chronic and incurable class increasing in a like ratio?

This lesson of the past should be the guide of the State in its future policy. It should be a wise, humane, economical, and settled policy. It should make unstinted efforts to stay this increase, and should afford every means to promote the recovery or improve the condition of each individual insane person. It should rigidly require of those public officials of our counties, cities, and towns, into whose hands all of the indigent and pauper insane first come, to immediately provide for their being

brought under such care and treatment as each case shall need.

It should even be remembered that many of the chronic insane may be so benefited by treatment as to be able to return to their homes, perhaps to help to support their family or themselves, or at least relieve the public from their support.

A short review of the history of the State in caring for its insane will show some of the defects of its present policy. About 1865 the State changed its policy in caring for the insane, and since then it has feebly tried to keep pace with its demanding needs, and now, in 1887, it is required to review its past and provide for the future.

The asylum at Utica was opened in 1843. Prior to that time the public insane were confined in poor-houses, jails, and the lunatic department of the New York Hospital. As the Utica Asylum had a capacity for but six hundred, and was soon full, and as the admissions soon rose to over four hundred a year, the chronic patients were sent back to their respective county poor-houses. By custom the county of New York early began to care for its insane, both acute and chronic, and by the same authority it still continues to care for them. By special statute Kings and Monroe Counties are allowed to care for all their insane.

For years the late Dr. John P. Gray, of the Utica Asylum, urged upon the legislature the evils of improper care of the insane in the poor-houses, and the need of enlarged State accommodations. In 1863 the State Medical Society took the matter up and presented it to the legislature. In consequence of all this agitation Dr. Sylvester D. Willard was appointed a State Commissioner to inquire into their condition and care. It was found to be most wretched, and in consequence of his report an act was passed establishing an asylum for the care of the chronic insane. Dr. Willard having died, it was called after him, and consequently we have the Willard Asylum.

This act established the policy of the State, which, with some modifications, is still continued. It required that all of the indigent and pauper insane should be sent to State asylums; the acute and curable to go to hospitals provided for their special treatment, and the chronic insane to be sent to Willard. It was hoped that all the insane would be removed from county houses, with the exception of New York, Kings, and Monroe counties.

How signally this hope has been defeated, and yet what a great work has been done by Willard, and later by the Binghamton Chronic Asylums. Success and failure stand side by side. In 1870 there were 1,326 insane in one poor-house, in 1886 there were 2,144. That is to say, in spite of all that has been done the insane in our county houses are increasing.

In accordance with this policy the State has now four asylums for the care of the acute insane, and two for the chronic class.

The first break in the Willard act came in 1871, when the State Board of Charities was authorized, in terms that really was compulsion, to allow counties to care for their chronic insane, provided they furnish suitable buildings and proper care. There are now seventeen counties thus caring for their chronic insane. In 1885 they had 1,620 inmates, while other counties not exempt from the act retained 524 in their ordinary poor-houses.

With these remarks the accompanying table will be of interest and easily understood. It is taken from the "Report of the State Board of Charities, 1886," page 131.

Two reasons operated to bring about a modification of the Willard law. First, the State did not furnish accommodations fast enough for the increase of the insane; and second, some counties with large numbers of insane to support were unwilling to pay for their care, which at Willard was at first a little over three dollars a week, but at the present time is but $2.26. The demand for exemption from these low rates still continues, the counties asserting that they can care for their insane at a lower rate.

One of the principal reasons for the Willard Asylum was "the aggregation of numbers, in order to divide the cost of support, so that the average cost might be reduced." The standard of care at our State asylums for the chronic insane is equal to that of our best asylums anywhere. It is idle to claim that our poor-houses with asylums (?) attached, caring for a few tens, or at the most a few hundreds, under the charge of an elected "keeper," can attain the Willard standard, and at the same time *lower* the cost of support. No one knows what it costs to support the insane in these county asylums, for there is no separation of accounts from the ordinary pauper department. Dr. Stephen Smith, the State Commissioner in Lunacy, thinks, all things considered, it costs the counties more in the end to keep these insane than to send them to Willard.

TABLE SHOWING THE NUMBER OF THE INSANE IN THE CARE AND CUSTODY OF THE INSTITUTIONS OF THE STATE.

Institutions.	October 1, 1885.	Total.
In State Asylums (acute).		
At Utica	568	
" Poughkeepsie	388	
" Middleton (homœopathic)	355	
" Buffalo	371	
		1,682
State Asylums (chronic).		
At Willard	1,810	
" Binghamton	751	
		2,561
In the Criminal Asylum (Auburn)	179	
" " Emigrant Asylum	29	
		208
In City Asylums.		
New York	4,040	
Brooklyn	1,360	
Poughkeepsie	4	
Monroe County (Rochester)	244	
		5,648
In County Asylums, exempt from the Willard Act	1,441	
" County poor-houses (not exempt)	570	
		2,011
In private asylums	597	
		597
Total		12,707

There are two great objects to be gained in caring for the chronic insane, aside from furnishing the merely physical comforts. Among them there are always some who will recover, and many more who can be greatly improved by proper treatment. But the tendency of chronic insanity is to greater physical, moral, and mental degeneration. The two great objects of care should therefore be to promote recovery or improvement, and to hold in check those influences that tend to lower the mental condition of the insane. Only the highest standard of care can accomplish these results. Do our county houses furnish such care? To prove that they do not, it is not necessary to go back to 1865, but to quote from the last published report of the State Commissioner in Lunacy.

He says: "The policy of creating small county asylums is wrong, both to the insane and to the tax-payers, . . . when it is remembered that fully one-half the cost of caring for the insane in the best asylums is charged to the account of attendants. . . . The greatest defect in county asylums is always found in the number and qualifications of attendants; . . . they curtail to a degree of absolute penuriousness in providing attendants. No defence of criticism is more common than the allegation that employment of more attendants would cost the officer his next election. . . . The coarser foods are well supplied, yet there is seldom discrimination of the varieties of food the insane demand. For months in the summer fresh meats are not supplied,

salt meats being the substitute; at other seasons the more common vegetables are deficient. . . . Bathing is not practised with regularity. . . . The moral tone is generally indifferent or low. Sabbath services are occasional, entertainments rare."

He gives notes of his visits to all exempt asylums, and proves his assertions, as a few quotations will show. "In one asylum," he says, "two patients are bathed in one water; C—— is confined to bed, which is not made up to-day and is wet, and patients are not bathed for three weeks for want of water." In another, "three and six are bathed in one water," and "restraint is left to the discretion of attendants." Of another he says, "that the day was hot, and the yard having neither shade-trees nor grass, was not a pleasant place for resort." Of another, that a woman with a child had charge of a ward, and in one ward he records five filthy patients found, and eight soiled beds made up.

It has been the writer's pleasure to know many keepers of county asylums, and he knows them to be warm-hearted and humane, and desirous of the welfare of their charge. As a rule, they acknowledge their ignorance of the care needed by the insane, and that they come into office without any special fitness by training, and they condemn a system it is not within their power to improve. Fancy a system that provides for the election, every three years, of a keeper of a poor-house, having a department containing 375 insane persons, and yet this is a part of the system and policy of our State.

The State should consider all the insane as its wards, whether confined in State, county, city, or private asylums, and require that they shall receive such care and treatment as will promote their comfort, recovery, or improvement.

County care should not be extended. If possible, the present small asylums should be broken up. All acute and curable cases should be sent to State asylums, and the right of New York, Kings, and Monroe counties in this particular should be taken away. All county asylums should be placed under local, non-partisan boards of managers, with the same powers that belong to managers of State asylums. All asylums of one hundred patients or over should have a resident medical superintendent. A certain sum of money should be appropriated for support by the County Boards of Supervisors, proportioned per capita to the number cared for. This rate should, in some way, be fixed by the State, and in no case should be less than that charged at Willard. No more asylums should be built or enlarged upon poor-house farms. Association with paupers is often painful to the insane, while the atmosphere of pauper management permeates the asylum.

The causes for the increase of insanity should be intelligently and scientifically studied, and efforts made to hold it in check.

The system successfully in practice in Scotland, and begun in Massachusetts, of placing the chronic and harmless insane to board in private families, should at once be begun in this State. It would in time give relief to our overcrowded asylums, and in a measure relieve the demand for more accommodations.

Dr. Smith thinks there are two thousand in our asylums that could be thus cared for. I would suggest that many of these cases could be cared for in their own homes, by families too poor to burden themselves with these insane relatives. Of course, to do this would require new legislation and careful State supervision.

In building new asylums and enlarging old ones the State should have a settled policy. Heretofore it has gone too much by hap-hazard, and often controlled by local influences. The extravagance of the past is likely to be matched by the parsimonious spirit of the present. Both are to be, and will be, regretted. In 1870 asylums were projected costing several thousand dollars a bed, and now the State is building for $250 a bed. The asylum at Willard, with a capacity for eighteen hundred patients, cost for land, building, furnishing, etc., $827 per patient. An asylum built so as to be pleasing to the taste, comfortable, and economical of management, and made permanent in its usefulness by thoroughness of construction cannot be built for less money. Asylum construction is undergoing great changes. The old plan of a continued block of buildings is giving way to the idea of a central building for the more disturbed class, and, scattered over the farm, detailed buildings, many of them small and home-like, for the quieter class.

To properly care for the insane there must be intelligent State supervision. Every insane person should be seen at least twice a year by a State Commissioner. All asylums should be frequently visited and thoroughly inspected. The State has outgrown its present system. One man cannot begin to do all that is required. To be sure, he is ably assisted by the State Board of Charities, but the care of supervising the insane is only one of its many duties. Besides, its members are not paid, and cannot give all their time. The surprise is, to those who know their work, that they do so much.

The State Commission in Lunacy should be increased to five, and certainly should not consist of less than three members. There should be at least two medical members familiar with the care of the insane, a lawyer, and a layman. Their term of office should be long, and their pay liberal. Competent men will not leave a practice or business and give all their time to the State without sufficient inducement. The appointment of such a commission should rest with the Governor and Senate. While it is too much to expect that political influences would have no weight in making these appointments, yet it is fair to suppose that other motives would influence the Executive; that the commissioners would not represent one political party, and that they would engage in no political management of the asylums.

With singular uniformity our governors have disregarded political considerations in appointing members of the State Board of Charities and managers of asylums. To this honorable example our present Executive is no exception. The appointment of Commissioners in Lunacy can, therefore, with safety, be left where it now, by the Constitution, belongs.

This is hardly the place to discuss at length the powers of such a commission. The English commission may well serve as our guide. They have done more than all other causes combined to place the English asylums in the front rank of the world. They possess visitorial and advisory powers only, and, after years of service, declare they can do more good with these than though possessed of compulsory power.

Our State asylums are controlled by a board of managers appointed by the Governor and Senate. These boards are, therefore, the peer of any body so appointed. Control would not be necessary over them. But the commission should have the utmost liberty of visitation, and power to gain any information desired of the manner of conducting State asylums, and only as a last resort have power to exercise command and control. Over county, city, and private asylums, uncontrolled as they are by the State, the commission should have the power to make rules and regulations for their administration, and to enforce them.

They should have an oversight of the individual patient to correct abuse, and attend to matters of commitment or unwarranted detention. They should possess a record of every admission, transfer, discharge, or death, so at any time they could tell where an individual patient could be found.

Thus briefly we have sketched the increase of insanity in our State, and discussed some of the problems of their future care. The time seems to have arrived when the State shall again fix its policy for caring for the insane, which should be a wise, humane, economical, and settled policy.

SOME COMPLICATIONS OF CHRONIC ENDARTERITIS.[1]

By WILLIAM BUCKINGHAM CANFIELD, A.M., M.D.,

MEMBER OF THE AMERICAN ACADEMY OF MEDICINE; CHIEF OF CLINIC FOR THROAT AND CHEST DISEASES, UNIVERSITY OF MARYLAND, BALTIMORE.

THE diagnosis of endarteritis chronica deformans, at its onset, is perhaps made only when a sudden complication makes it too apparent. As to its probable cause—whether gout, syphilis, chronic lead-poisoning, abuse of alcoholic drinks, chronic narcotism, etc.—we are often unable to speak with certainty for a single one. In its varied course and insidious approach, chronic endarteritis makes itself known by the hardness, inelasticity, and tortuousness of the superficial arteries, slowly creeping on from centre to periphery of the vascular system; or, its progress backward to the heart may cause another train of symptoms. In the latter case the sclerosis of the aorta becomes a

Sclerosis of the aortic valves, and the attention is attracted by a systolic or diastolic murmur heard over the aortic area, and by an enlarged left ventricle. In the great majority of cases the important etiological factor in acute endocarditis is acute articular rheumatism, and, indeed, so often is this the case, as we know, that one of the first questions asked of a patient with valvular trouble is, if acute rheumatism has ever preceded this attack of heart disease. But the two important points in the diagnosis between endocarditis from acute rheumatism and endocarditis from endarteritis is that in the former the mitral valve is by preference affected, and in patients generally under forty years of age; whereas in the latter case chronic endarteritis attacks those over forty, and spreads by contiguity from the aorta to the nearest valve, the aortic, and even if the mitral valve is here affected, it is in company with the aortic valve, whereas after acute rheumatism the mitral is often alone affected.

Another complication is an affection of the aortic valve, due to sudden over-distention of the heart. Peacock[2] made the first important communication on this point. He reported cases of incompetency of the valves from hard work, stretching the valves, as well as cases of direct injury from sudden strain. Albutt[3] and, later, Myers[4] published papers on the same subject, from cases observed among soldiers. In many treatises, monographs, and works on diseases of the heart, this subject has received scarcely more than a mention. Seitz,[5] Foster,[6] Fraentzel,[7] Da Costa,[8] Flint,[9] Quain,[10] and a few others have given more or less detailed accounts of this affection, but it was not until this past year, when Leyden[11] published his painstaking and interesting article, that the subject has been exhaustively treated. He says that the connection between arterio-sclerosis and bodily overexertion has not been proved, but it is very probably true.

The working-classes are particularly prone to this, and the men naturally more than the women. In this case the stiffness and incontractibility of the sclerosed vessel offers too much resistance to the column of blood thrown on it during a violent exertion, and the blood being forced back into the already full left ventricle, causes a sudden distention, with rupture of the aortic valves. In this case we find insufficiency, and occasionally stenosis, of these valves.

A third and frequent complication of arterio-sclerosis is aneurism. This complication may be a sequela of the preceding one. The aorta is atheromatously degenerated, and the left ventricle is hypertrophied. In this condition of things a powerful effort of the hypertrophied left ventricle forces the blood through the aortic valves and upon the aorta, thus causing an aneurism. And even before the sclerosis has extended to the heart, a sudden and violent exertion, as in the majority of cases, causes an aneurism in the atherosed aorta in that part which, by virtue of its position has the greatest strain brought upon it.

The exact definition of the term aneurism is not always clear. Richet[1] says that many aneurisms are due to a dilatation of the vessel without a pathological change in the coats, and that the destruction of the sac does not take place until a long time after the distention.

Cornil and Ranvier,[2] on the other hand, carefully point out that it is not the result of a single mechanical action upon a healthy vessel which caused the distention, but that these aneurisms are always developed in vessels which have been for a long time the seat of inflammation. Dr. Wilks[3] considers the terms "aneurism" and "dilatation" as expressions of degree, and also seems to be of the opinion that the larger vessels are generally first diseased and then distended, and this without any reference to the number of coats involved.

The microscopical examination of the aneurismal walls of the aorta does not always give satisfactory results. The three coats are supposed to take part in the formation of an aneurism. Ranvier and Cornil,[4] however, have stated that an aneurism of the aorta consisted of the interna and adventitia only, the media having entirely disappeared. I have noticed in specimens that the three coats could be recognized in that part of the artery bordering on the aneurism, but in the aneurism itself the separation between the coats was not clearly marked, notwithstanding the fact that in one specimen the aneurism had just begun to form, the patient having died of an intercurrent disease. Birch-Hirschfeld[5] says that on the border of an aneurism of the aorta the three coats can be distinguished, but toward the middle of the tumor the media disappears first and then the interna and adventitia cannot be distinguished, and, indeed, there is often only a hyaline layer in place of the three coats.

Having once found a pulsating tumor of the chest, the diagnosis of aneurism is not so difficult, as a non-aneurismal tumor of the chest is extremely rare. The difficulty is to find out its exact site. Da Costa[6] says we can do little more than conjecture the position of a thoracic aneurism, because a tumor within the chest leads to such displacements that its relations to the surrounding parts cannot be clearly ascertained during life. The most valuable information we can obtain is from a study of the physiological changes from the symptoms of disturbed function. Indeed, the correctness of our conclusions will depend almost entirely upon that of our interpretation of these symptoms

The following case, which came under my care, is interesting on account of some of the signs and symptoms noticed. The meagreness and incompleteness of the history, however, is due to the fact that the patient failed to reappear, and thus escaped an inevitable post-mortem, which would have confirmed or corrected the diagnosis:

Mrs. B——, aged forty-seven, a pale, spare woman, rather under-nourished, came to me complaining of inability to use her voice, and wished to have a supposed

laryngitis and bronchitis treated, which she said she had had for some length of time. She complained of pain in the left side of the chest and left arm, and said that her heart "fluttered" very much and seemed to rise up in her throat when she was excited. She was decidedly short of breath, and spoke scarcely above a whisper. On examination a pulsating tumor was observed at the left sterno-clavicular articulation, and was very perceptible to the eye and hand. The tumor, she said, came suddenly after exerting herself during a convalescence from typhoid fever. The following points were obtained: Pain over the cardiac region, especially on pressure, dyspnœa, dysphagia, occasionally œdema and want of sensibility on the left side, displacement of the trachea to the right side. There was also dilatation of the left pupil, almost complete absence of the right radial pulse, and absence of aneurismal bruit in the right carotid and subclavian arteries, which bruit, however, was audible on the left side. The diagnosis of aneurism was at once made, but the exact site could not with certainty be determined. On palpation and percussion the heart was found to be higher than normal, the apex being in the fourth intercostal space and to the right of the left nipple, near the sternum, that is, directly above its normal position. There was apparent to the eye and hand much palpitation. Percussion was extremely painful. On auscultation the heart-sounds seemed to be much quickened, but otherwise normal in character. She had complained for some time of a dry cough and of hurried respiration after the slightest exertion. On questioning her, she said that by her first husband she had had two miscarriages and one child, since dead. She had had sore throat (a not unusual occurrence), and her hair had been coming out. She did not remember having had rheumatism. Although there may not be sufficient proof that her trouble was of syphilitic origin, still, without making a diagnosis as to the cause, iodide of potassium with syrup of the iodide of iron were exhibited in gradually increasing doses. After several weeks under this treatment the mydriasis disappeared, the swelling was apparently reduced in size, and her voice returned for a short time.

The history of the case, unfortunately, stops here, as she passed out of my care while I was absent from the city, and has probably succumbed long since to the aneurism, the exact position of which can be conjectured only. Before reviewing the symptoms and signs present in this case, it might be well to glance at some of the statistics on aneurism.

The following figures from Lisfranc [1] give the number of cases collected by him for the different ages:

Age, Years.	Number of Aneurisms.
13	1
15 to 20	3
20 to 30	17
30 to 40	29
40 to 50	37
50 to 60	17
60 to 70	3
70 to 80	3

Much more numerous are the statistics for the different vessels. Thus, Hodgson [2] reports the following cases:

Ascending aorta, arch, and innominate artery	21
Descending aorta	8
Carotid	2
Subclavian and axillary	5

Of the 551 cases of Crisp [3] there were of the

Thoracic aorta	175
Abdominal aorta	59
Subclavian artery	23
Carotid artery	25
Popliteal artery	137

[1] Lisfranc: Article Aneurysme, du Nouveau Dict. de Méd. et de Chir. prat., t. i.
[2] Hodgson: Treatise on the Diseases of Arteries and Veins. London, 1815.
[3] Crisp: Diseases of the Blood-vessels. London, 1847.

These were in part distributed as follows:

Age, Years.	Number of Aneurisms.
20 to 30	71
30 to 40	198
40 to 50	129

In the London Museum [1] the collection of aneurisms is as follows:

Thoracic artery	207
Abdominal artery	42
Popliteal artery	50
Subclavian artery	12
Carotid artery	9

In Sibson's [2] collection there were 880 aneurisms of the aorta, 703 of which were of the thoracic aorta and distributed as follows:

Ascending aorta (including 87 at the valves of Valsalva)	193
Arch	120
Descending aorta	72

Lancereaux,[3] Baillu,[4] Hayem,[5] and others all agree that the thoracic aorta is most frequently the seat of aneurism. Crisp [6] also says that the anterior and right side of the aorta is most frequently affected, and that the cause is a sudden and violent contraction of the heart. All authors agree that men are more liable than women to this form of aneurism, and naturally, on account of their occupation. The proportion may be stated as about one woman to eight men.

In reviewing the different signs and symptoms, in the endeavor to interpret them, some light may be thrown on the situation of the aneurism.

Pain.—The pain was felt on the left side and down the left arm. It was probably due to the pressure of the aneurism on branches of the brachial plexus, and also to pressure caused by general œdema.

Dyspnœa.—This might be due to several causes: (1) simply to a diminution in the size of the thoracic cavity; (2) to pressure on the left bronchus or trachea; (3) to pressure on the recurrent laryngeal nerve of the left side, in which case we should have a neurotic dyspnœa. As no laryngoscopic examination was made, it might be supposed that the three causes were present. From her manner of breathing and the size of the aneurism, I am inclined to think that the last two causes were present.

Œdema.—This was undoubtedly caused by pressure on some venous trunk, most probably the innominate vein.

Mydriasis.—The mydriasis was caused by pressure upon a branch of the cervical sympathetic (cilio-spinal). This agrees with several other points in the history which go to show that the aneurism had not grown to a very large size. The fact that the pupil on the left side was dilated would tend to show that the fibres of the cervical sympathetic going to the musculus dilatator pupillæ were simply irritated and not destroyed, in which latter case the pupil would be contracted, since the oculomotorius and sphincter pupillæ would have no opponent. The cases reported recording an affection of the pupil generally refer to a contraction, and not to a dilatation, of the pupil. Gairdner [7] reported a case of aneurism of the aorta which projected up into the neck, causing a contraction of the pupil on the affected side. But on further noticing this case it seems that the patient was taking large doses of opium, which certainly could not fail to have an effect on the pupil. Robertson [8] reports a case of division of the cervical sympathetic, with contraction of the pupil on the affected side. Dr. John Reid [9] was the first to point out this inequality of the pupils in case of tumors of the neck interfering with the cervical sympathetic.

Hurried respiration.—This was caused by pressure upon the left pneumogastric nerve, which pressure also caused the increased rapidity of the heart-beat.

Dysphagia.—This may be explained on the same ground as the pressure on the trachea.

Want of sensibility on the left side.—This was probably due to the œdema, as well as to the pressure on the sensory nerves.

Almost complete absence of right radial pulse.—This is the most difficult sign to understand. Generally the radial pulse on the affected side is indistinct or absent, and in this case we must either record this sign as an exception which may possibly occur, or try to show that the aneurism extended in some way over to the right, or was actually situated on the right side of the thorax, in spite of all the apparent proofs to the contrary. Crisp [1] says, if there is an obstruction to the circulation in the subclavian or innominate artery, there is usually a difference in the pulse of the two sides of the body, the radial pulse of the affected side being less distinct. If, however, the arteries contain no fibrinous deposit, and their calibre be not diminished, the pulsation on the affected side may be stronger.

The condition of the heart.—The valves were found to be normal, and the ventricles apparently not hypertrophied. This is a rare condition in case of an aneurism of the aorta, especially of the ascending and arched portions. In many of such cases reported, the aortic valve was affected. Key,[2] in speaking of the reaction of aortic aneurisms on the heart, says he has not yet met with a case in which an aneurism of the aorta produced a hypertrophy of the muscular substance of the left ventricle, and in another report [3] he found an aortic insufficiency in four cases out of seventeen, and no case of stenosis; and his deduction was that if the valves were healthy the aneurism exerts no influence on the heart.

This review of the signs and symptoms, together with the age of the patient, her history, and the above statistics, would point to an aneurism whose probable seat was in the aorta. As an aneurism at the valves of Valsalva produce so few symptoms, and so easily escapes detection, this part may be eliminated. The ascending aorta may be excluded, because an aneurism here would in all probability be on the right side; and even if an aneurism of the ascending aorta were present, and the aneurismal sac pressed over upon the left side of the heart, causing the symptoms related, there would be a bruit or throb in the right subclavian or carotid, which the history shows was absent. The descending aorta may also be excluded; and as the left side was principally affected, it was most probably (unfortunately it is not certain) an aneurism occurring at the anterior and inferior portion of the left part of the arch, opposite to where the left carotid and subclavian are given off. Of course such a diagnosis can be based upon hypothesis alone.

In looking at the etiology of this case, it would not be right to deduce that, because the iodides caused a general improvement, therefore the cause was specific. That the iodides do cause an improvement in many such cases has been witnessed lately by Huchard,[4] of Paris. He records a number of patients suffering from atheroma of the arteries and chronic arteritis, as well as valvular trouble from atheroma, in all of which amelioration and recovery were brought about by the use of the iodides, and particularly of the iodide of sodium. He says these were true cases of organic heart trouble in patients not anæmic. He also particularly affirms that the iodides, in his experience, are not efficacious in every form of valvular disease, but only in chronic so-called sclerotic inflammation of the lining membrane of the heart and the arteries.

NOTE.—Since writing the above, an article by Beverley Robinson, M.D., on this subject, has appeared in THE MEDICAL RECORD, February 26, 1887.

A SUBSTITUTE FOR THE ORTHODOX PESSARY.[1]

BY W. GILL WYLIE, M.D.,

NEW YORK.

HAVING no paper to read, I will substitute a few remarks upon a subject that I have often wished to bring before the Society, as it has been of much practical benefit to me—viz., the abuse of the pessary. I am entirely satisfied that in the text-books too much stress is laid upon the matter of displacements as being the cause of uterine disease. I mean, that I think it is a mistake to regard simple displacement of the uterus as a disease. It is very frequently associated with serious disease, but, as a rule, if the disease is cured, the displacements are of little consequence.

I never did adopt the use of the stem pessary, having felt satisfied that it is of little practical value, and that it is risky.

I recognize the fact that retroversion is often a serious complication, especially when the uterus is large or when the parts are very much relaxed; or when the uterus prevents the free egress of the fecal matter. But it is not a disease.

It seems to me that there will be a radical change in the teaching of the text-books upon this subject. The thing has been entirely overdone.

Long ago I was convinced that the pessary was only a helping instrument; that if it relieved the patient, it simply relieved her, and that its use alone was not good practice. Some years ago Dr. Sims introduced glycerine as an agent to be used in the vagina, with the view of producing a watery discharge. He also found that if it was left there forty-eight hours it would very frequently undergo some kind of ferment or change resulting in a vaginitis, and do more harm than good. He also mixed with it alum, and found that alum increased the tendency to the watery discharge.

A number of years ago I took up the subject, but accomplished little until boro-glyceride was brought out.

A standard formula that I use with great success in my practice is, one ounce of boro-glyceride and enough pure glycerine to make a pint, and one ounce of sulphate of alum (if I want an astringent; if not, the acetate of aluminum).

Then I found, if I took cotton in a soft, fluffy bunch, tied it with a string, saturated it with the solution, and put it up against the uterus, that, often in six hours, that piece of cotton would be rolled into a ball which would rest against the urethra and set up an irritation. I saw then that this would not do, and it occurred to me to take the cotton and roll it up over a rubber tube; after it had been rolled to the size desired, I tied the end of it firmly with a string. That answered very well. Later I secured some borated cotton of Eimer & Amend, which comes in flat sheets. I found that by rolling this firmly into a roll about one inch in diameter and two inches long, and tying it with a good flax string at the end, that I had cotton in such shape that, if it was thoroughly saturated and put into the vagina, it would retain the shape for four days. It would stay where it was put, and in four days it would be almost in the identical position. I also found that, for the first twenty-four hours after its introduction, there would come away a profuse watery discharge, from four to eight or nine ounces, in proportion to the congestion of the uterine vessels.

The method of introduction is as follows: Place the patient in Sims' position, then introduce Sims' speculum; after saturating the cotton thoroughly, pull back the perineum and push the cotton against the cervix, letting the cervix rest on the anterior part of the cotton. Hold the cotton in that position and remove the speculum.

[1] Remarks made before the Northwestern Medical and Surgical Society of New York, April 27, 1887.

The anterior portion would then lie in the direction of the pubic bone.

It acts as a pessary, except with more certainty, because the perineum, springing up against the cotton, keeps it in place.

The action of the boro-glyceride is to prevent any kind of ferment or change. It has a good effect in catarrhal conditions, and it does not interfere at all with the action of the glyceride and alum in producing the watery discharge. I am satisfied with this as a means of keeping the uterus in place, and at the same time as tending to cure any uterine congestion. I leave it in the patient for twenty-four to seventy-two hours; then wash out the coagulated mixture, and on the third or fourth day make a second application. If there is much of a dragging sensation, I tell the patient to wear it two or three days.

The manner in which this acts as a curative agent, it seems to me, is perfectly plain. The watery discharge which comes from the glands of the mucous membrane, not only of the vagina but of the uterus itself, forces a rapid circulation through the pelvic vessels; it acts in the manner of a very hot poultice, by getting up an active circulation through the tissues, thus bringing fresh and healthy blood into the tissues; and in that way it helps to eliminate disease.

You can theorize about this as much as you please, but practically it is a very great success.

I can take a case of subinvolution of two or three months' standing, with the dragging sensation and more or less leucorrhœal discharge, and in from three to six weeks I will reduce the uterus to its normal size, using nothing else but this cotton. It has enabled me to do almost entirely without pessaries. I use this treatment in cases where Dr. Emmet recommends hot water and iodine. It is very much quicker in its action than the latter method, and instead of the patient being kept in bed she is enabled to go about.

I often use bismuth on these pledgets, as it is a good antiseptic; also other substances, such as iodoform, balsam of Peru, etc.

ON THE USE OF PILOCARPIN MURIATIC IN YELLOW FEVER.

ABSTRACT OF A PAPER BY E. HABERSMITH, M.D.,

EGMONT KEY, REFUGE STATION, FLA.

SOME years ago I had an experience with pilocarpin in beriberi, in the San Francisco Marine Hospital, that caused me to resolve that if ever I came in contact with yellow fever again I would give the drug a fair trial in that disease. The first refugees arrived on July 11th; on the 15th there was a death with black vomit, and another death—a relapse—on the 20th. Neither of these cases afforded fair opportunity for trial, but on the morning of the 16th I found a man, sixty-four years of age, in the beginning of an attack—temperature, 104.3°. I put him between blankets and administered one-fourth of a grain of pilocarpin hypodermically. In a few minutes water was pouring out of him. In the course of an hour he had three copious evacuations of the bowels. Evening temperature, 101°; pulse, 92. Next morning, temperature, 99.4°.; pulse, 80. Evening temperature, 96.1°; pulse, 72—*a fall of* 8½ *degrees*. Next day his pulse and temperature were normal, and he would have left hospital if I had permitted it.

The next case occurred on August 1st, and was a repetition of the first. Surprised and delighted at the success of my experiment, I said to myself, This cannot be yellow fever, and reported both cases as malarial paroxysms.

Then occurred a curious incident. I was temporarily absent from the station, and on the morning of August 4th a hospital attendant was taken sick with fever. He was immediately put upon the orthodox calomel, castor-oil, and mustard foot-bath treatment, and developed as perfectly a typical case of yellow fever as ever was seen—spongy, bleeding gums, albuminous urine, fever lasting four days, great prostration, pulse in convalescence as low as 54 beats; and I asked myself what would have been the history of the case had he been treated as the other two men were treated.

I soon had light. On August 12th there arrived, two days from Key West, a family—man, wife, and six children. Parents both sick with fever—taken sick the morning of arrival. I hurried them into hospital and put them under pilocarpin treatment, with the result of having them both convalescent within forty-eight hours. Then a child, aged ten, was taken, on the morning of the 14th. Temperature, 102°; pulse, 120; administered one-eighth grain. Evening temperature, 104.3°; pulse, 140. Dose of pilocarpin not large enough; repeated it, giving about one-third larger dose, causing free emesis as well as profuse diaphoresis. Next morning her temperature was 99.2°, a fall of over five degrees; her pulse, 120. During the day they both became normal, and that was the end of her fever and sickness. Pilocarpin should be used in the first stage, in doses sufficiently large to produce a decided effect—either emesis or catharsis, preferably both. My theory of the *modus operandi* is not that the drug has any specific effect, like quinine in malaria, but that it sets every excretory function in the whole body actively at work, and the enormous flow of water from the skin reduces the fever on precisely the same principle as the temperature of the water in a water-monkey is reduced—namely, by rapid evaporation.

The treatment is thoroughly scientific and rational, the result of much thought and observation, and applicable to the whole range of Southern bilious fevers. They can be broken by pilocarpin, promptly administered; that, followed by quinine, to prevent recurrence, will surprise and delight both physician and patient.

It has long been known that pilocarpin, given at the commencement of an ordinary paroxysm of intermittent fever, would stand the paroxysm on its head, so to speak—that is, it brings the sweating stage to the front, and there is little or no fever. I believe I am the first to demonstrate the great value of the drug in yellow fever; indeed, judging from my cases here, yellow fever becomes a very trifling matter.

DIET IN DISEASE.—The relation of food to certain abnormal states is well known, to disregard which would be fatal to the success of any method in therapeutics. There are conditions, in fact, in which diet, and not medicine, is the leading indication of treatment. We have repeatedly cured chronic flatulence, occurring in aged persons with enlarged livers, by eliminating sugar from their dietary. All know the superiority of lean meat and skimmed milk over any form of medicine in diabetes; the benefit of a milk and farinaceous diet in catarrhal affections of the stomach; of cooked milk (boiled half an hour or more) in enteritis and ulceration of the mesenteric glands; of fresh vegetables in scurvy; of fruit, and bread made from unbolted wheat-meal in chronic constipation, etc.—*Ed. N. Y. Medical Times* (liberal homœopathic).

THE WORK OF THE CHOLERA IN FRANCE AND SPAIN.—M. Mahé has published in the *Annales d'Hygiène* an elaborate statistic of the recent cholera epidemic. In France the number of deaths from the affection in 1884–85 exceeded 13,000, which gave 1 death in 3,000 inhabitants. In Italy 30,000 persons succumbed, or 1 in 900 of the population. Spain gave a much higher mortality, 180,000, or 1 in 100. Thus it is computed that the three countries lost 220,000 inhabitants out of 600,000 attacked during those two years, and the material loss in one way or another exceeded twenty millions sterling.—*Providence Medical Journal.*

found embedded in the fæces. During the time of its stay in the alimentary canal the child had complained slightly a few times of pain in the stomach, but outside of this no symptom was produced, and the spoon passed through the anus without causing pain. The spoon was very much discolored from sulphur."

Progress of Medical Science.

Salix Nigra as a Sexual Sedative.—In the *British Medical Journal*, July 30, 1887, Dr. Hutchison, of Glasgow, writes: "In many women pain in the ovarian region is a constant attendant upon the menstrual epoch. In some this is due to organic disease, but in a large number it is one of the manifestations of the neurotic temperament. Such cases are met with in all degrees of severity, from a slight amount of discomfort along with indications of globus hystericus, up to hystero epilepsy in its most pronounced forms. It has always been a slur upon our profession that, when a method of treatment becomes popular or fashionable, other methods are entirely discarded. At present, massage and isolation from relatives is the popular mode of treatment, and drugs occupy a secondary place, if, indeed, they have any place at all. Pecuniary difficulties, however, stand in the way of isolation or massage ever reaching the masses, and drugs will always be in employment. Several drugs are in daily use against the ailment, but with only partial success, and it is with the view of bringing before the profession a remedy which in my hands has produced results which I never had before while I was employing the bromides, valerian, assafœtida, etc., that I have sent this short notice. Salix nigra, or the pussy-willow, is a tree growing from fifteen to twenty feet high. It is met with along the streams in the Southern States of America, and is credited with possessing tonic, carminative, and stimulant properties, besides being an astringent and antiperiodic. In the 'Transactions of the Texas State Medical Association,' Mr. Pain reports many cases treated successfully with the drug. He prescribed it in cases of ovarian hyperæsthesia, uterine neuralgia, etc., and also in spermatorrhœa and nocturnal pollution. His verdict upon the drug is that it is a powerful sexual sedative, similar in its action to bromide, but without its depressing qualities. I obtained a supply of the fluid extract, and have been employing it for some months. The most numerous class of cases in which I exhibited the drug were women of a nervous temperament, in whom the nervous irritability reaches its height at the menstrual period, when, along with the general *malaise*, is added a very decided pain in one or other ovary. They also suffered from hemicrania, the pain being situated above the left eyebrow, and resembling the feeling as if a nail were being driven into the skull (clavus). Many of them, too, complained of a pain underneath the left breast, and extending round to the back. On one or two occasions I have noticed patients complaining of the above symptoms, and in only a moderate degree, under favorable ventive medicine; 5, example, long-continued anxiety, gr and the discovery of new remedies; 5, abdominal (antiseptic?) surgery; 6, diagnostic art.

It appears to us that neither of the distinguished gentlemen referred to above has answered the question very completely. If Sir William Hamilton had taken the trouble to peruse the writings of Hippocrates and physicians of his time, he would have been a little surprised at many of their therapeutical ideas. If Sir William, for example, having a quinsy, could have called in Hippocrates, the learned professor would have been bled in the arm and sublingual veins, he would have been purged, given warm gargles, his head shaved, had a way stronger. I have also given the drug in two cases of nocturnal emissions with marked benefit. The pollution ceased entirely while the drug was being taken and for several months thereafter. Virile power and passion were not much, if at all, diminished, but the relief from the ailment gave them great satisfaction."

A Peculiar Condition of the Tongue resembling Beef-steak.—In the *Australian Medical Journal*, Dr. Henry records three cases seen by him during the last few months, where the tongue was of a deep red color, fissured in every direction, and bearing the most striking resemblance to a piece of raw beef-steak. The surface of the organ seemed to be completely denuded of epithelium and papillæ, there being no sign of fur or coating. In each case the condition was chronic. The patients were females, and were all brunettes, who suffered from dyspepsia in an aggravated form. According to the author, this condition is generally associated with a good deal of nervous irritation and very great debility, with prostration. The treatment is not easy, but by paying attention to the general health and correcting any irregularities, and especially of the female genital organs, a good deal may be done toward curing a very rebellious condition.

Surgical Scarlatina.—In a recently published lecture on surgical scarlatina, Dr. Hoffa, of Würzburg, has reported two instances of this affection, the rash having appeared in the first of these cases after extravasation of urine, and in the other after a wound of the perineum. After full recognition of the facts that English surgeons were the first to direct attention to this association, Dr. Hoffa points out that it will be seen, on looking over the numerous recorded cases of so-called surgical scarlatina, that in many of these there is no evidence of true scarlatinal infection. These cases, it is stated, may be analyzed and arranged under four categories. In the first the rash was nothing more than erythema, due simply to vaso-motor disturbance, an analogous condition of the local congestion on the surface of the skin, which is often observed, appearing early and vanishing rapidly after delivery or some minor operation. The second class is made up of instances of toxic erythema, occurring in the course of from twenty-four to forty-eight hours after some cutting operation, and after injury with or without wounding of the skin. This rash, in its mode of onset, its course, and its clinical significance, resembles any erythematous medicinal rash. It comes on without any premonitory signs, and is accompanied by gastric disturbance and high fever. The rash occurs in the form of fine red points, or large isolated patches, with intervening clear spaces of healthy skin. It is met with only on the trunk and extremities. As a rule it disappears spontaneously within twenty-four hours, and is not followed by desquamation. It is very probably caused through the absorption of wound-secretions, or the presence of crushed tissue in the circulation, and, in some instances, may be due to the action of fibrin-ferment. A similar rash is sometimes observed in the neck and trunk after the administration of chloroform, and also in cases of general poisoning by carbolic acid and corrosive sublimate. The rash in the third group is the result of septic or pyæmic infection, and of much more serious import than in the previous groups. It usually occurs in the form of a disseminated erythema, affecting simultaneously or successively different regions of the surface of the body. The nature of this rash is usually very evident, as the erythematous patches are often associated with miliaria and pustules, with purpuric spots and with ecthyma. There is one form of pyæmic rash which it is very difficult to distinguish from true scarlatina. On the third, fifth, or seventh day after the first attack of rigors this rash usually appears at the wound or open surface, and in the course of the two following days spreads as a bright and evenly diffused redness, often limited to one side of the trunk. This rash disappears

for a moment under digital pressure, and is usually accompanied by œdematous swelling of the skin. It vanishes in the course of the fourth or fifth day, and is often followed by desquamation, and sometimes by purulent infiltration of the subcutaneous cellular tissue. This variety of exanthem is probably due to capillary embolism through micro-organisms. Besides these three groups of rashes, all of which have been wrongly regarded as instances of surgical scarlatina, there is a fourth variety which comprises cases in which the rash is really the result of the infection of the organism with the poison of scarlatina. Dr. Hoffa says that the diagnosis of scarlatina can be accepted only when, in addition to the characteristic exanthem, there is present at least one of the other morbid conditions that go to form the group of symptoms of the eruptive fever, these morbid conditions being angina, swelling of the submaxillary glands, desquamation, and nephritis. The diagnosis will, of course, be rendered absolutely certain if other persons become infected with scarlatina through contact with the subject of the case in question. Although in a very large proportion of the reported cases of true surgical scarlatina the infection had taken place before the date of the injury or operation, a sufficient number of instances have been observed to prove that such infection may be of subsequent occurrence. There are two modes in which this may occur. Either the subject of the wound may, through proximity to some other person who is suffering from scarlatina, acquire the disease in the usual way, by infection through the digestive or respiratory tract, or the infection may start in the wound, the rash first appearing at the margins of the open surface, and spreading without interruption to other parts of the surface of the body. Reference is made to a number of cases which prove that infection must have taken place by an open surface. With one exception, the subjects of these cases were adults, and such persons as were likely to have been previously often exposed to the contagium of scarlatina without having been infected. This fact would lead to the conclusion that the presence of a wound must constitute a predisposition to become susceptible to the poison of scarlatina. It is held by English pathologists that any local inflammatory process may also constitute such a predisposition, and that this predisposition depends on certain changes in the nervous system set up by the wound or local inflammation. The author believes that the tendency of the subject of an open wound to contract scarlatina is due to the ability of the scarlatinal micro-organisms to enter by this wound in such numbers as to overcome the resistance of the tissues. He accounts for the previous immunity of such patients by assuming that the micro-organisms either fell upon sound, unbroken skin, or entered the body in too small a quantity to overcome the resistance made to their development by the elements of its tissues. In reference to the statement of Sir James Paget, that in cases of scarlatina in the subject of a wound the incubation period is usually shortened, Hoffa, while pointing out that such a fact would support his view, asserts that this period is sometimes prolonged in cases of surgical scarlatina. In surgical cases the characteristic symptoms of scarlatina, such as the rash, the angina, the desquamation, and the nephritis, are often much modified, and one or more of these conditions may be absent. But, it is added, there is a great tendency, in ordinary cases of scarlatina in which there is no wound or external surgical lesion, to deviate in many ways from its typical course. The name of surgical scarlatina should be applied only to those cases in which the scarlatinal affection starts from a wound.—*Volkmann's Sammlung Klinischer Vortrage.*

Alkaline Mercurial Soap as an Absorbent.—Dr. Svetukhin, chief of Professor Lashkevich's clinic in St. Petersburg, states that various preparations have been recently employed in the wards for the purpose of promoting absorption of pleuritic effusion. Iodine ointment is too mild and too slow in its action to answer the purpose, and the odor of iodoform ointment is so strong that it interferes too much with the comfort of the other patients, and so is found to be unsuitable for hospital practice. It was found that iodine ointment could be advantageously supplemented by soft-soap (sapo kalinus viridis) inunctions, or by rubbing in unguentum hydrargyri. The most valuable of all applications for this purpose was, however, found to be a preparation called sapo kalinus hydrargyrosus, which is made by mixing in certain proportions metallic mercury, unguentum hydrargyri, caustic potash, and olive-oil, so that the resulting soap contains a third of its weight of mercury, the unguentum hydrargyri of the Russian Pharmacopœia containing half its weight of mercury. This is agitated with hot water so as to form a good froth and lightly rubbed into the skin. It has the advantage over unguentum hydrargyri in being much more easily rubbed in, in not irritating the skin and thus causing eruptions, and, lastly, in not so rapidly setting up stomatitis or salivation. From half a drachm to a drachm of this mercurial soap is used for each inunction. After from six to ten applications some diminution may be detected in the effusion, and after twenty inunctions the whole is usually found to have disappeared. Of course, favorable results can only be looked for in cases of simple effusion; they cannot be obtained in empyema.—*The Lancet.*

The Skin Affections that Accompany Malaria.—Dr. Retiwzew gives the following statistics, taken from the observation of 2,000 cases of malaria (*The London Medical Record*): 1, Roseola occurred in 2.5 per cent. cases, chiefly in the first eight days of the disease; 2, an erythema in large spots in three per cent.—it came in small and large patches, accompanied with itching and burning, and lasted from a few hours to two days; 3, urticaria in 4.5 per cent. of the cases—frequently it accompanied erythema; 4, herpes facialis in twenty two per cent., mostly on the lips and nose; 5, herpes zoster occurred only once in 2,000 times; 6, petechiæ were frequently found in severe and long-standing cases; 7, purpura simplex often accompanied malarial cachexia.

Cannabis Indica in Diarrhœa.—Drs. Bond and Edwards draw attention to the value of cannabis indica in cases of summer diarrhœa or cholera morbus. The formula generally employed for an ordinary adult is: Tincturæ cannab. ind., ♏x.; liquor morph., ♏v. to x.; spirit. ammon. arom., ♏xx.; sp. chloroformi, ♏xx.; aq., ad ℥j. To be repeated every one, two, or three hours, according to circumstances. No food should be taken for several hours, and only a little brandy-and-water to drink. By this treatment rapid relief is given. The great depression, frequent stools, vomiting, and cramp-like pains quickly disappear, and in two or three days the patient is quite well. The cannabis appears to act by increasing the astringent and anodyne properties of the morphine, by its stimulating effect on the nervous system, improving the general tone, and enabling the system to quickly overcome the depression. This drug is also very useful in cases of subacute gastro-enteritis, but it has not been found very good in cases of tuberculous diarrhœa.—*The Practitioner.*

of fruit, and bread made from unbolted wheat-meal in chronic constipation, etc.—*Ed. N. Y. Medical Times* (liberal homœopathic).

The Work of the Cholera in France and Spain.—M. Mahé has published in the *Annales d'Hygiène* an elaborate statistic of the recent cholera epidemic. In France the number of deaths from the affection in 1884–85 exceeded 13,000, which gave 1 death in 3,000 inhabitants. In Italy 30,000 persons succumbed, or 1 in 900 of the population. Spain gave a much higher mortality, 180,000, or 1 in 100. Thus it is computed that the three countries lost 220,000 inhabitants out of 600,000 attacked during those two years, and the material loss in one way or another exceeded twenty millions sterling.—*Providence Medical Journal.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, October 8, 1887.

HAS THE PRACTICE OF MEDICINE IMPROVED?

AT the last meeting of the British Medical Association, Professor Gairdner, of Glasgow, set himself the task of answering the old query of Sir William Hamilton: "Has the *practice* of medicine (the art as distinguished from the science) made a single step since Hippocrates?" In the last issue of the *Asclepiad*, Dr. Benjamin Ward Richardson presents an epitome of the great advancements in practical medicine, preventive and curative, by the physicians of the Victorian era. The title of Dr. Richardson's review itself shows that he would answer Hamilton's query very emphatically in the affirmative. Professor Gairdner, who gives a similar affirmative answer, gives, nevertheless, a very meagre catalogue of the achievements. They are, he says:

"1. The increased value attached to hygienic remedies, and the recognition of the fact that the insanitary conditions which produce disease tend to its continuance and retard recovery; 2, the abolition of frequent and routine venesection, which has gone hand in hand with a greater trust in the self-healing processes in acute diseases—*vis medicatrix naturæ*; and, 3, a more rational treatment of epidemic fevers, easily digestible foods having been allowed to replace alcoholic stimulation, which had itself displaced copious venesection and other depletory remedies." He contends also that, in general terms, there is a greater "stability" in medical practice, a stability which will in the future prevent extensive revolutions in practice by ill-considered theories.

Dr. Richardson answers the question by enumerating six distinct "advancements," here presented in chronological order: 1, The treatment of the insane; 2, preventive medicine; 3, anæsthesia; 4, therapeutical changes and the discovery of new remedies; 5, abdominal (antiseptic?) surgery; 6, diagnostic art.

It appears to us that neither of the distinguished gentlemen referred to above has answered the question very completely. If Sir William Hamilton had taken the trouble to peruse the writings of Hippocrates and physicians of his time, he would have been a little surprised at many of their therapeutical ideas. If Sir William, for example, having a quinsy, could have called in Hippocrates, the learned professor would have been bled in the arm and sublingual veins, he would have been purged, given warm gargles, his head shaved, had a cerate and fomentations put to the neck, and given water and "the juice of ptisan" ("Regimen in Acute Diseases," vi.). If he had had dropsy, he would have received a draught of cantharides; if he had had dysentery, boiled beans and madder shoots, etc. In addition to this, whatever his complaint, if acute, he would have been treated on an erroneous theory of coction and crisis. Indeed, no one who has read Hippocrates would ever ask so foolish a question as that propounded by the late Scotch professor. We have more than advanced in our art—we have created it.

THE OPENING OF THE COLLEGE OF PHYSICIANS AND SURGEONS.

THE exercises attendant upon the opening of the new building of the College of Physicians and Surgeons last week were simple, but dignified and impressive. The story of the College's long career of usefulness was told by the President of the Faculty, and the promise, with its new equipment, of doing a greater and better educational work was appropriately dwelt upon. There can be no doubt that medical education in this country will make vastly greater strides, simply through the fact that at least a few institutions are now able to teach students in the very best manner. The people are learning that there are doctors and doctors, and the best taught get a quicker recognition, and, other things being equal, soon distance their competitors. The magnificent endowments of the College of Physicians and Surgeons place New York easily first among the great teaching centres of the country.

BORACIC ACID AND LEUCORRHŒA.

WE have already referred to the successful results reported by Dr. N. F. Schwartz (*St. Louis Courier of Medicine*, June, 1887), in the treatment of leucorrhœa, by packing the vagina with boracic acid. Leucorrhœa is an indefinite term, but it probably means, in most cases, that there is a catarrhal condition of the vagina and endocervix, either, or both. For these states, the standard prescription is injections, or injections combined with local applications of iodine, carbolic acid, etc., to the cervix. The results are generally fairly good when the patient can be persuaded to carry out the treatment faithfully. But American women do not take kindly to the system of elaborate gymnastics necessary for proper douching; consequently leucorrhœas are more often not cured than otherwise. Dr. Harold N. Moyer, who has tried the boracic-acid method, states (*The Medical Standard*) that the discharges can be stopped with from two to three applications of the acid. He says:

"The method advocated by Dr. Schwartz is substantially that followed in suppurating otitis; it was the success of the treatment in this latter affection that led him to apply it to the vaginal cavity. The method recommended, and the one followed by the writer, is first to irrigate the vagina with water as hot as can be borne; then a speculum is introduced, and the walls of the vagina are carefully dried with pledgets of absorbent cotton. Sufficient boracic acid is then poured through a cylindrical glass speculum to fill and completely distend the vault of the vagina and surround the vaginal portion of

the cervix. I greatly prefer the larger crystals, as they dissolve slowly and the effect is more prolonged. The crystals are held firmly in place by small tampons of absorbent cotton, supported by a large aseptic wool tampon."

Two cases are reported, illustrating the application of the method.

News of the Week.

Dr. Lefferts' Dinner to Mr. Lennox Browne, of London.—Dr. George M. Lefferts, of this city, gave a dinner and reception at Delmonico's, Monday evening, October 3d, to Mr. Lennox Browne, F.R.C.S. Ed., of London, the well-known laryngologist. Dr. William Ord, F.R.S., of London, shared the honors with Mr. Browne. The dinner was, as usual with the host, everything it should be. Twenty-eight representative medical men were present, and vied with the genial host in makthe occasion a thoroughly enjoyable one.

Vermont Medical Society.—The seventy-fourth annual meeting of the Vermont State Medical Society will be held in the New Court Room, State House, Montpelier, Vt., on Thursday and Friday, October 13 and 14, 1887.

Some of our Chicago Medical Colleges are energetic, at least. The College of Physicians and Surgeons of that city accompanies its opening with a column and a half notice of the school and the various members of the faculty, illustrated with cuts. The Rush Medical College, also, celebrates at equal length and with similar richness of illustration. If they are faithful presentments of the distinguished teachers, we lament the decay of manly beauty in Chicago. The practice of using the teaching institutions for purposes of personal advertisement, as is done in the two notices referred to, is pernicious and likely to lead to grave results. The general practitioner asks himself why he should not be able to advertise with impunity also; and a tendency to lax practices is encouraged—practices which, if carried to their logical and legitimate end, degrade the profession to the level of quacks, or, at the best, to that of mercenary and enviously competing tradesmen.

Homes for Medical Students.—The Middlesex Hospital College has had erected a building designed expressly for affording to medical students a comfortable home in close proximity to their work. The building is under the charge of a warden and steward. The usefulness of such an institution is very apparent, and it would be a matter of great congratulation if some of our colleges here would undertake a similar work. Medical students are, as a rule, obliged to live in cheap boarding-houses, without such comforts or social surroundings as best promote their health, happiness, or their manners.

A Death from Cerebral Embolism during Administration of Ether.—A patient of Dr. D. Hayes Agnew died while under the influence of ether. The heart beat for three-quarters of an hour after respiration ceased. An autopsy by Dr. Formad showed pachymeningitis, with atheromatous arteries. There were minute blood-clots in many of the cerebral vessels, one of them being situated in the medulla, involving the respiratory centre.

At the Opening of one of our large medical colleges, on September 29th, the learned orator is reported as follows: "He devoted a good deal of time to impressing on his audience the importance of chemistry, and, in an atmosphere that was positively stifling owing to the absence of any ventilation, he paid a very glowing tribute to the laws of hygiene and the necessity of a higher appreciation of improved sanitation."

Opening Exercises of the College of Physicians and Surgeons.—The College of Physicians and Surgeons celebrated the opening of its new building with a banquet, September 29th, and appropriate exercises at the College. The dinner was as large as Delmonico's banquet-hall could accommodate. Dr. C. R. Agnew presided, and speeches were made by Mr. Depew, Mr. Cornelius Vanderbilt, Dr. William Pepper, and others. The exercises at the College opened with prayer. Dr. Dalton then made an address, giving the history of the College. In 1806, he said, the Medical Society of the County of New York, in order to promote the advancement of medical science, asked for the incorporation of a medical college, and in the year following this was accomplished. The first lectures were given in a building on what was then Robinson Street, now Park Place. Fifty-three students attended the first session, 76 the second, and 82 the third. The second year the College was removed to Magazine Street, now 553 Pearl Street. Nicolas Romeyn was the first President. The College removed to Barclay Street, and then to Crosby, where its usefulness became very great. In 1826 all the professors resigned and formed another institution, which lived only four years. Fifty years after its founding the College became the medical department of Columbia. In 1856 the building at Twenty-third Street and Fourth Avenue was secured. It had been arranged that Joseph H. Choate should deliver the inaugural address, but owing to sickness in his family he was unable to be present. Dr. William H. Draper took his place. He referred to the superiority of medical instruction and opportunities for medical investigation in Europe during the past, but believed that, with the increased interest in science and the help of private gifts, great advances were now being made here without government help. Dr. Draper presented the bronze bust of William H. Vanderbilt, the gift of Trustees and Faculty. Mr. Vanderbilt had been sitting for this on the day that he died. The bust is by J. Q. A. Ward. It is placed in the main hall, where it can be seen by the students as they enter the building. Portraits of Drs. Hosack and Mitchell were also presented, and one of Dr. John C. Dalton, the present President of the College. The building, which is the best equipped in the world, is a brick structure, designed to facilitate that combination of didactic instruction with laboratory work which is essential to a modern scientific training. It consists of a southern wing, measuring 140 by 43 feet, along Fifty-ninth Street; a northern wing, 76 by 43 feet, along Sixtieth Street; and a middle portion, 96 by 55 feet, connecting the other two.

The southern part contains the administrative department, with conversation, reading, and smoking rooms, and a room where disarticulated skeletons are kept. On the second and third floors are professors' recitation and demonstration rooms, a laboratory, and the Swift Physiological Cabinet. The top floor is devoted wholly to work upon the cadaver. In the evening it will be lighted by electric lights. It contains thirty-six tables, at which one hundred and eighty students can dissect at once. The northern portion of the building is given up to laboratory purposes. In the middle building are two large lecture rooms, which will hold four hundred and fifty students each. The remaining space is taken up with work-rooms in the various departments.

The Vanderbilt Clinic, at Sixtieth Street and Tenth Avenue, is connected with the main college by a covered passage-way. It was built and the land provided by the sons of Mr. William H. Vanderbilt, as a memorial of their father, and provides a fully equipped dispensary service for the sick poor. It also contains a theatre for clinical lectures, and small rooms for instruction and examination. The Sloane Maternity Hospital is at Fifty-ninth Street and Tenth Avenue. It is a lying-in hospital with thirty beds, given by William D. Sloane, whose wife, a daughter of William H. Vanderbilt, has made its beds free in perpetuity.

The Distinguished Dermatologist, Professor Unna, while in New York City, is said to have been called in consultation over the case of a well-known and wealthy lady here. The fee received, $6,000, is probably one of the largest ever obtained by a dermatologist.

Gleditschine—not Stenocarpine—as the name of the new anæsthetic has been finally determined, ought to be at once adopted in place of the incorrect term "stenocarpine." The drug, we learn, is as yet very expensive and somewhat difficult to get.

Mr. Richard Quain, one of the editors of "Quain's Anatomy" and "Quain's Atlas," author of the "Anatomy of the Arteries," and the oldest surgeon in London, died on September 15th. Mr. Quain was long known as a successful surgeon, teacher, and author, and the "Anatomy" which he assisted in editing is still the best text-book which we possess on this subject in the English language. Mr. Richard Quain is not Dr. Richard Quain, author of "Quain's Dictionary," and a gentleman still very much alive.

Death of Professor von Langenbuch.—This distinguished Berlin surgeon died last week. For several years he had retired from the active duties of his professorship, but had continued to take an interest in surgical and scientific matters. Not long ago he was made a baron in recognition of his long and remarkable services to surgery and education.

A Permanent Emergency Corps.—The medical corps organized for emergency and ambulance service during the Constitutional Centennial at Philadelphia has formed itself into a permanent body. Its constitution declares the object of the association to be the rendering of free aid as a corps to the municipality in public emergencies requiring medical or surgical assistance, through or under its medical director. The association is to be divided into three classes, the first consisting of the active members, or emergency corps, the second of honorary and associate members, and the third of the lady patronesses.

Country Doctors and Experimental Work.—Dr. N. Senn began practice as a country doctor in Wisconsin, but has managed to do as much experimental surgery as anyone in the country. It is not the opportunity always, but the man.

The Baneful Influence Locally of Medical Colleges.—The editor of the *American Lancet* thinks that the influence of medical colleges upon the profession, in the towns in which they are situated, is bad. He refers, we presume, to cities of 200,000 inhabitants or less. The effect upon the fee-lists is shown by a comparison of that in Cleveland, where there are three medical colleges, with that of New Jersey, a State distinguished by having no medical college. He says: "In Cleveland, an office visit is twenty-five to fifty cents, in New Jersey one to ten dollars. In Cleveland a visit from the family physician is one dollar, no extra charge for an hour or two detention, no charge for prescription to other members of a family. In New Jersey a visit from the family physician is from one to ten dollars, a dollar extra being charged for every hour's detention."

Baths, Gymnastics, and Mountain-climbing are measures for the treatment of heart disease which largely occupy the attention of German physicians interested in these diseases. An intelligent study and exposition of such measures is needed on this side of the water.

Both Sydenham and Boerhaave, great names in medicine, asserted that acute pneumonias were rarely cured without the abstraction of forty ounces of blood. This treatment was pretty successful also.

Health Board Doings.—The following resolutions have been passed by the Board of Health:

Resolved, That on and after October 1, 1887, the consideration of all diseased animals coming under the jurisdiction of this Department be and is hereby referred to the Division of Contagious Diseases of this Department.

Resolved, That on and after October 1, 1887, Dr. Cyrus Edson be and is hereby transferred from the position of Chief Inspector of Food and Chemical Analysis to that of Chief Inspector of Contagious Diseases, and that his salary be increased to $3,000 per annum.

Resolved, That on and after October 1, 1887, the position of Chief Inspector of Food and Chemical Analysis in this Department be abolished, and that Mr. E. M. Martin, the chemist of the Board, be given charge of the duties of that office, and that his salary be increased to $2,000 per annum.

Resolved, That on and after October 1, 1887, Mr. E. M. Martin be and is hereby directed to report to this Board, a plan of action which shall contemplate a careful scrutiny of all food and drink commodities of this city, for the purposes of detecting the existence of diseased or adulterated conditions of them.

The late Dr. J. C. Hutchison.—At a meeting of the medical staff of the Brooklyn Hospital, September 24, 1887, the following minute was adopted: "The long and active connection of our friend and associate, the late Dr. Joseph C. Hutchison, with the Brooklyn Hos-

pital, was characterized by earnest and unfaltering devotion to its interests. His pre-eminent professional skill, his conservative and accurate judgment, his large and varied experience, his genial manner, and the inspiration of his native kindness and Christian manhood were ever ready for his professional associates as well as for those who sought the shelter of this institution for help, and were ever intent on all suggestions that served to keep the Brooklyn Hospital first and most liberal among the charitable institutions of the city. Contributing as he did by his dignified presence and his many graceful accomplishments to the adornment and advantage of the enterprise, culture, and benevolence of the city, the Brooklyn Hospital was nearer to his heart than any other, and to it were given his utmost care and the best of his gifts.

"D. E. KISSAM, *President.*

"ARTHUR R. PAINE, *Secretary.*"

THE LATE DR. ALONZO CLARK.—At a meeting of the Board of Managers of the New York Society for the Relief of the Widows and Orphans of Medical Men, held September 21, 1887, Dr. Gouverneur M. Smith presiding, the death of Dr. Alonzo Clark, a late associate and benefactor, having been announced, it was

Resolved, That this Board has heard with sincere sorrow of the death of Alonzo Clark, M.D., LL.D., and, in view of his eminent service to the medical profession as scholar, instructor, and counsellor, deems it fitting to place on record an expression of its appreciation of his eminent ability, singularly upright professional and private life, and of his zeal and ability as an investigator and lecturer.

Resolved, That the medical profession owes to him much of value in the advancement of medical science, while his ever loyal devotion to those needing his help and advice make his name one to be honored both by personal and professional friends.

Resolved, That while there is in his death a sense of bereavement to those who knew him best, there is also the satisfaction of a long and honorable life, filled with results capable of accomplishing much of good to his fellow-men.

Resolved, That a copy of these resolutions be sent to the family of Dr. Clark, and that they also be inscribed in full upon the minutes of this Board, and be published in the medical journals.

(Signed,) WILLARD PARKER, M.D.;
JOHN H. HINTON, M.D.;
ELLSWORTH ELIOT, M.D.,
Committee.

At a special meeting of the Board of Trustees of the College of Physicians and Surgeons, held on the 20th day of September, 1887, the following resolutions were passed:

Whereas, We have been called upon to deplore the death of our late associate, Dr. Alonzo Clark, a former President of the College of Physicians and Surgeons, and for more than thirty years a distinguished professor in the institution; therefore,

Resolved, That we hereby record our eminent regard for the dignity and influence of Dr. Clark's personal character and our high appreciation of his attainments and distinction as a teacher.

Resolved, That the College of Physicians and Surgeons is largely indebted to Dr. Clark, as one of the most learned and skilful physicians of his time, for its high reputation as a school of medicine, and that it is both appropriate and gratifying for us, as trustees of the institution, to express our sense of the obligation. Also,

Resolved, That we offer to the family of the deceased the assurance of our respectful sympathy in their deep affliction.

Resolved, That the foregoing resolutions be inscribed upon our minutes; that a copy of them, signed by the President and Registrar, be transmitted to the family of the deceased; and that they be furnished for publication to such medical journals as the Registrar may elect.

At a regular meeting of the Medical Board of St. Luke's Hospital, held Wednesday, September 24th, the following sentiment was ordered to be entered upon the minutes.

It has pleased the Master to call to his reward our late associate, Professor Alonzo Clark, M.D., who early in the history of St. Luke's was appointed consulting physician, and for many years was president of our medical board.

We, his associates, feel that we cannot allow him to depart from among men without formally recording our high appreciation of his character and example.

Of impressive stature and dignified presence, he commanded attention and inspired respect.

Throughout his long professional life he was a teacher of great influence, and did much to elevate and improve the standard of medical instruction.

A man of broad and liberal culture, he frowned upon pretence and quackery, so that those who practised such arts shrunk away abashed from his presence.

We, who have known him long and well, feel keenly his loss, and sympathize in the grief of those near and dear to him who have been left to mourn, but "not as those without hope."

GEO. A. PETERS, M.D.,
Pres. Med. Board.
A. BRAYTON BALL, M.D.
ALBERT A. DAVIS, M.D.

THE LATE DR. JARED LINSLY.—*Whereas*, The New York Society for the Relief of the Widows and Orphans of Medical Men has recently been bereaved by the death of one of its benefactors and its former President, Dr. Jared Linsly;

Resolved, That the Board of Managers desires to place on permanent record its appreciation of his private and public virtues, of his distinguished medical career, and of his exemplary Christian character.

Resolved, That by his pecuniary contributions, as well as by his counsels, he has ever shown such a liberal spirit that he has been among the foremost in promoting the benevolent objects of the Society.

Resolved, That a copy of this preamble and resolutions be entered upon our minutes and be sent to the family of the deceased with an expression of our sympathy in their great bereavement, and be sent to the medical journals.

(Signed.) ISAAC E. TAYLOR, M.D
WM. N. BLAKEMAN, M.D.
W. C LIVINGSTON, M.D.

Reports of Societies.

NEW YORK STATE MEDICAL ASSOCIATION.

Fourth Annual Meeting, held in New York, September 27, 28, and 29, 1887.

TUESDAY, SEPTEMBER 27TH—FIRST DAY—MORNING SESSION.

THE fourth annual meeting was held at the Hotel Brunswick, the opening session being called to order by THE PRESIDENT. The first business was

THE REPORT OF THE COMMITTEE OF ARRANGEMENTS,

which was read by DR. CHARLES A. LEALE, of New York. The speaker extended a warm welcome to the members.

THE PRESIDENT'S ADDRESS

was then read by DR. ISAAC E. TAYLOR. The speaker referred to the past success of the Association, spoke of the bright prospects of its continued success, urged upon his associates the necessity of discharging to the best of their ability the duties devolving upon each of them, and expressed in feeling terms the sorrow occasioned by the death of a number of worthy and prominent members.

He then entered upon the main subject of his address—

LUPUS SERPIGINOSIS OF THE CERVIX UTERI AND GENITALIA OF WOMAN.

The speaker described a case which had come under his observation, and exhibited a cast of the external genital organs. The case was first seen by him in 1885. The disease began in the cervix. Its course was interrupted for a time by a period of comparative health. The morbid process then renewed its activity, extending to the vulva, and involving the clitoris and urethra, where it appeared in the hypertrophic form, and finally resulted in the death of the patient.

The speaker then dwelt upon the rarity of this affection occurring in the female genital organs, the fact of its existence being doubted by some, and spoke of the differential points from cancer, tubercular disease, etc. The question as to whether the disease was due to a special organism was still unsettled. There was as yet no fixed method of treatment, which varied according to the views of the individual physician, and according to the indications present in each case. The chief point to be borne in mind was not to inflict injury upon the healthy tissues beneath and around the diseased part. In this case nitric acid had been the substance employed.

The first paper, entitled

THE USE OF HOT WATER IN SURGERY,

was read by DR. THEODORE R. VARICK, of Jersey City. The author had already read two papers, before different societies, on this subject, and his object now was to reply to criticisms, and to give further statistics in support of the method. He used water of a temperature only a little below the boiling point. It was brought directly from the kettle, and was applied by means of a clean sponge or linen cloth. By the time it reached the wound it was probably of a temperature of about 183° F. Its effect was to coagulate the albumen, and to hermetically seal the blood-vessels, thus preventing the entrance of pathogenic germs. As long as bleeding continued there was little danger of septic infection; but when the oozing had ceased, if the vessels were patent, this danger became real. Another advantage in the use of hot water was that it was a cardiac stimulant, and tended to avert the danger of the shock which was present in greater or less degree in all major operations.

The author then presented the statistics of amputations, collected from various sources, in upward of six thousand cases, which showed an average mortality of a little over thirty-two per cent. Of fifty-three amputations performed by him since 1879, in which he had used his hot-water method, there had been only three deaths, or a mortality of less than six per cent. Most of these were cases of railroad injuries. In one, death was due to angina pectoris, in another to secondary hemorrhage, and in only one to septicæmia. In this case, Dr. Varick believed, the septic poison had gained entrance through a wound in the other foot, which had not been operated upon.

DR. JOHN D. MCGILL had used hot water in twelve cases of amputation, and had not lost a single patient. It was not sufficient to apply simply warm water, as some who failed to understand the principle of this method had done, but the water should be at a temperature very near the boiling point.

The next paper was read by DR. CHARLES S. WOOD, of New York. It was upon

BICHLORIDE OF MERCURY: ITS USES AND ABUSES.

The speaker feared that this poison would do more harm to the human race than good, unless great caution were observed in its employment. Some years ago, before much was known of the germicidal properties of corrosive sublimate, he had employed it in certain cases of phthisis, with, he believed, good effects. While he did not believe that the drug was efficient in medicinal doses to destroy the bacillus tuberculosis within the human organism, he thought it probably exerted a beneficial influence in counteracting the poisonous effects of the ptomaines secondarily developed.

Another class of cases in which the author had seen benefit from the use of bichloride of mercury were those of Bright's disease. In several cases he believed the drug had caused relief of the urgent symptoms, and had materially prolonged life, enabling the patient to pursue his ordinary duties with comfort. Dr. Wood cautioned his hearers against the too frequent and careless use of bichloride of mercury, not only in internal medication, but in surgical dressings as well. It could never arrest any acute or infectious disease, when given internally, for doses of sufficient size to destroy the micro-organisms would first kill the patient.

DR. NATHAN JACOBSON, of Onondaga County, followed with a communication entitled

A CONTRIBUTION TO THE STUDY OF HIP-JOINT DISEASE.

The author was of the opinion that hip-joint disease was usually a result of traumatism, and that the occasional accompaniment of pulmonary tuberculosis afforded no proof that the hip disease was primarily tubercular in origin. He reported two cases. In one of them there had been signs of pulmonary tuberculosis which disappeared after the joint symptoms were relieved by operation; but whether the pulmonary trouble was secondary to the affection of the joint, or whether the two were concomitant but independent affections, the author was unable to decide, although he was convinced that the disease of the lung was largely influenced by the joint disease. He maintained that the existence of tuberculosis of the lungs should not be considered a contraindication to operation in hip-joint disease.

AFTERNOON SESSION.

The order for the afternoon session was a

DISCUSSION ON THE MANAGEMENT OF COMPOUND DISLOCATION OF THE ANKLE-JOINT.

DR. E. M. MOORE, of Monroe County, opened the discussion by a paper in which he showed that writers from the time of Astley Cooper down to the present had now and then advocated the adoption of more conservative methods of treatment in compound dislocations of the ankle joint. He, however, believed that, even at the present day, surgeons were less inclined toward conser-

vatism than they should be. He presented a brief report of five cases which had come under his observation, in none of which had he found it necessary to perform primary amputation, and in none had there been a fatal issue. Four recovered with useful limbs; in one the dressing had caused some strangulation of the tissues, gangrene resulted, and necessitated amputation. A perfect result was obtained, by a friend of the writer, in the case of an elderly lady. The patient recovered with a perfect limb and was able to walk without a limp. He would never perform a primary amputation except in an extreme case.

Dr. Uri C. Lynde, of Erie County, discussed the first question, viz.:

WHEN SHOULD AMPUTATION BE PRACTISED, AND WHEN SHOULD OTHER METHODS BE EMPLOYED?

As a result of his own experience, the speaker had been led to divide these cases into two classes. If there were simply contusion in connection with the dislocation, and if that contusion involved only a limited area on one side of the ankle, he would not amputate, even though it was possible that sloughing might occur. But if the contusion were extensive, covering both sides of the ankle, and especially if there were extensive injury of the bones, it would be necessary to amputate at once. In case of rupture of the posterior tibial artery, if the injury to the bones was not extensive, the wound should be treated conservatively. But if the bone-injury was marked, the astragalus being comminuted, rupture of the artery would suggest the propriety of amputation. The same rule would apply in cases of rupture of the anterior tibial artery. Rupture of the nerves might in a particular case lead to an unfavorable result, but this accident by itself was not a sufficient indication for amputation.

Primary amputation, even at the present day, was not a perfectly safe procedure, though it was fair to say that the advances being made in modern surgical methods would do more to lessen the dangers of amputation than it had, or could, toward rendering the conservative method safe. But if conservatism failed to save the foot, there still remained a resort to secondary amputation. If the surgeon must err at all, it would be far better to err on the side of conservatism.

Dr. Joseph D. Bryant, of New York, then discussed briefly the second point,

IF AMPUTATION IS TO BE PERFORMED, AT WHAT POINT SHOULD IT BE MADE TO RENDER THE STUMP MOST USEFUL, THE RISKS TO BE ENCOUNTERED BEING EQUAL?

He thought the choice of operation lay between Syme's amputation, and amputation at the junction of the middle and lower thirds of the leg. Syme's amputation should be preferred whenever the condition of the soft parts was such as to warrant a hope that a serviceable stump could be procured by the usual flap-procedure. If, in amputation of the leg, the bones were divided just above the malleoli, the stump would not be oval, but would terminate in a bulbous extremity upon which an artificial limb could be fitted only with great difficulty. Pyrogoff's amputation was objectionable for this reason.

Dr. Charles W. Brown, of Chemung County, discussed the third question,

SHOULD THE LUXATION BE MERELY REDUCED, OR SHOULD SOME BONY TISSUE BE REMOVED, AND IF SO, HOW MUCH?

He favored removal when the bone protruded considerably and could not be replaced without inflicting additional injury upon the soft parts, and also when a portion of the periosteum had been destroyed, or when the head of the bone had been crushed or broken. As to the amount of bone to be removed, much would depend upon the nature of the injury. If the articular surface of the bone had forced its way through the soft parts, the safest plan is to saw it off. But if the joint were simply open, the dislocation being incomplete, the wound should be thoroughly cleansed and dressed antiseptically, no portion of the bone being removed.

The last point proposed for discussion was,

WHAT DRESSING AND AFTER-TREATMENT WILL CONDUCE TO THE BEST RESULT WITH LEAST RISK TO THE PATIENT?

This was discussed by Dr. Frederic S. Dennis, of New York, who premised his remarks by assuming that the question of amputation had been considered and that it had been decided not to amputate. He believed that it was consistent with real conservatism to perform a partial resection with the view of rendering the wound aseptic. The entire limb, from the toes to the knee, should be washed, shaved, scrubbed, and irrigated with an antiseptic solution preparatory to the examination of the wound. The original wound should then be enlarged, the interior of the joint thoroughly explored, and a counter-opening made. All loose pieces of bone and cartilage, and any foreign bodies which might be present, should be removed. All the severely contused or shreddy soft parts should be cut away, and the joint the thoroughly irrigated with a warm bichloride solution. A rubber drainage-tube should be carried directly through the cavity. The joint being thoroughly cleansed, the parts should be enveloped in wet towels, wrung out of bichloride solution. If it was found impossible to reduce the dislocation, because of the resistance of the tendons, they should be divided subcutaneously. The selection of the splint employed should be governed by the special indications in each individual case. In most cases, the author preferred the plaster-of-Paris bandage. The danger of its being applied too tightly could be avoided by the use of cotton. After a final irrigation, iodoform should be sprinkled over the parts, a thin strip of iodoform gauze be put over the wound, and a wet bichloride bandage, folded double, should be wrapped around the ankle and leg. The plaster-of-Paris bandage could then be snugly applied over a layer of borated cotton. Four sheet-iron strips might be inserted, with the object of strengthening the plaster splint. A fenestrum should be cut at the side of the drainage-tube at the end of the third day, and when the tube was withdrawn it should be done under continuous irrigation.

The speaker thought that this form of dressing possessed many and great advantages over any other.

Dr. Nathan Bozeman, of New York, then read a paper entitled,

THE TREATMENT OF CYSTITIS BY COLPO-URETRO-CYSTOTOMY, IRRIGATION OF THE PELVIS, OF THE KIDNEY, AND INTRAVAGINAL DRAINAGE.

He described a new instrument, devised by himself, by means of which the urine passing through a vesico-vaginal fistula could be conducted directly to the receiving vessel, thus avoiding irritation of the vaginal mucous membrane. By means of this instrument he had been able to pass a rubber catheter up through the ureter into the pelvis of the kidney, and thus obtain irrigation of that organ. The procedure was not difficult, was painless, and safe. He had repeatedly practised irrigation in this manner, and had allowed his patients to return to their homes immediately afterward. The method, he believed, opened up a new field in the treatment of diseases of the kidneys, as it was free from the objections pertaining to nephrotomy and nephrectomy.

Dr. Henry D. Didama, of Onondaga County, then read a paper on

METHODS OF APPLYING COLD.

He first reviewed the ordinary methods, and then described his own, which, he claimed, possessed the advantage of being effectual, comfortable to the patient, and inexpensive.

He laid a rubber sheet on a mattress, and on one lateral half of this a folded cloth wrung out of cold water and a pillow. Over these were placed another rubber sheet and an ordinary sheet, on which the patient was to lie. When it became necessary to renew the cold, cloths wrung out of cold water should be placed between the rubber sheets on the other side of the bed, and the patient could then be lifted over by wooden bars attached to the edges of the upper sheet.

Dr. Robert H. Sabin, of Albany County, then presented a communication on

GALL-STONES.

The author spoke with authority, as he was himself subject to gall-stones and biliary colic. He took the ground that gall-stones were formed only when the fluids of the organism were in an alkaline state, as indicated by the alkalinity of the urine. The speaker related the case of a woman who occasionally passed large numbers of gall-stones the size of hulled peanuts, and closely resembling them.

Wednesday, September 28th—Second Day—Morning Session.

Dr. Uri C. Lynde, of Erie County, read a paper on

DISLOCATIONS OF THE ELBOW-JOINT.

The author had met only with neglected cases of this dislocation. When the dislocation was allowed to remain unreduced, there was not only great deformity but also considerable impairment, if not loss, of the function of the joint. Dr. Lynde first discussed the reduction of recent dislocations of the forearm upon the arm. In cases in which the brachialis anticus muscle was uninjured, it was the chief reliance of the surgeon in his efforts to effect reduction. There were but two indications in the reduction of the dislocation—the first being to raise the coronoid process from the olecranon fossa, and the second to aid the brachialis anticus muscle in drawing this process forward. There were two methods—the one by over-extension and traction; the other by flexion and traction. By the first method the coronoid is *lifted* from the olecranon fossa; by the second it is *rolled* out of it. In both methods, traction from the wrist is practised to aid the brachialis anticus in drawing the humerus into normal position. Should this muscle be torn, traction will be aided by the biceps. In cases of very recent luxation, the patient is himself able to reduce it; but after some weeks or months reduction is very difficult.

Dr. Lynde deprecated the practice of over-extension in old cases, for he believed that the integrity of the vessels was thereby endangered. Flexion, however, was sult of his observations was that terebene is a valuable remedy in these affections. He had given it in doses of ten to fifteen drops three or four times a day.

Dr. Douglas spoke of the good effect produced by the use of terebene in tubercular laryngitis.

Dr. Wallian thought that if the influence of the drug was due to the peroxide of hydrogen set free, larger doses would be necessary. He did not regard the danger to the blood-vessels and nerves as very real.

Dr. Carman, of New Haven, thought it unnecessary to put the knee in the bend of the elbow while practising reduction of this joint, just as it was needless to insert it in the axilla in order to reduce a dislocation of the shoulder. The thumb, he maintained, answered equally as good a purpose as the knee.

Dr. John W. S. Gouley, of New York, followed with

AN ADDRESS ON NOSOGRAPHY.

The speaker reviewed the work of nosographers in the past, and criticised at some length many of the terms employed in the nomenclature of disease, and especially of disease of the male genito-urinary organs. Among other faults, Dr. Gouley spoke of the term "genito-urinary system," for which he contended the phrase "genito-urinary apparatus" should be substituted. He did not present a complete nosographical system, but said that the object of the essay was rather suggestive. He urged the general adoption of a nosography founded upon a rational basis, and hoped that teachers might be brought to a realization of the necessity of a better system of nomenclature.

The address was referred to a committee consisting of Drs. A. L. Carroll, of Richmond County; E. M. Moore, of Monroe County; and J. Cronyn, of Erie County.

Afternoon Session.

The order for this session was a

DISCUSSION ON TYPHOID FEVER.

Dr. Alfred L. Carroll, of Richmond County, opened the discussion with a paper in which he propounded seven questions. The first question was,

DOES THE TERM "TYPHOID FEVER" PROPERLY INCLUDE ALL THE VARIETIES DESCRIBED BY OBSERVERS; OR ARE THERE OTHER STILL UNDIFFERENTIATED, CONTINUED FEVERS COMMONLY GROUPED UNDER THIS HEAD?

In discussing this question, Dr. Carroll thought that some of the varieties of typhoid fever, as described by observers, differed from each other as widely as the general group differed from typhus fever. The general experience of the profession was that implicit reliance should not be placed upon any one clinical symptom in diagnosticating the disease, for even the autopsy did not always clear up the diagnosis. He thought we were justified in speaking of a specific exanthematous fever with local lesions in the intestinal glandular apparatus, apparently developed only from changes which took place in the excreta of a previous existing case. Until a clearer idea of the pathology of this disease was obtained, he thought it might be entitled enteric fever.

Many well-authenticated cases of adynamic fever had occurred in isolated rural districts, where no connection with a previous case could be discovered, but it remained to be proven that we were justified in classing such cases as enteric fever. Adynamic fevers, resembling typhoid or enteric fever in the clinical history, could be traced to filth-fermentation.

Speaking of

THE PROPHYLAXIS OF TYPHOID FEVER,

he said the most common source of danger was the water. We could not always rely upon the filtering power of the soil, for this might be, and often was, overtaxed. Artificial methods of purification were not reliable, but the simplest way was to boil the water for at least half an hour. As regarded the water-supply of communities, the only wise rule was to see that there was no possibility of contamination of the source of the supply by drainage.

Dr. Carroll then referred briefly to

THE INDICATIONS FOR TREATMENT OF TYPHOID FEVER.

He insisted that pure air, pure water, and a pure soil were as essential in the treatment as they were in the prophylaxis of the disease. Nutrition should be maintained. Cold baths might be useful in certain cases, but he did not favor their routine adoption, and he was doubtful also concerning the utility of antipyrin in the long run; at least it might be questioned whether relapses did not occur more often after this drug had been employed.

Dr. E. G. Janeway, of New York, discussed the first question, which, however, he changed as follows:

DO WE ENCOUNTER IN THIS STATE A FORM OF CONTINUED FEVER NOT DUE TO TYPHOID POISON, AND LIABLE TO BE MISTAKEN FOR TYPHOID FEVER?

The author admitted having had doubts, as must every physician of experience, regarding the nature of

the poison which had excited the fever in certain cases. Typhoid fever was no more bound in its course to rigid rules than were pneumonia and other diseases. The speaker had seen in the course of a single year as many as twenty cases of typhoid fever which had been called remittent, typho-malarial, and simple continued fever. He did not think types had changed so much as had the diet and the treatment. He thought that the diminished frequency of diarrhœa was largely due to this latter fact. The firmest believers in the view of the divisibility of the cases of typhoid fever into many types were those whose practice was such that it was difficult to get an autopsy. Many cases of true typhoid fever in isolated places were looked upon as malarial, typho-malarial, etc. As regarded the latter, he was of the opinion that a large proportion of the cases seen in this latitude, and diagnosed as typho-malarial, were cases of pure typhoid fever. He knew of no reason why one should admit the existence of a typho-malarial cause of an acute or separate disease process, but thought that this supposition was based upon certain cases of typhoid fever in which the course of the disease had been modified by a previous malaria. It would be wiser to stick to the nomenclature of typhoid fever and look upon the malarial element as a complication.

He then took up the second question,

IS TYPHOID FEVER ALWAYS THE PRODUCT OF A SPECIFIC CONTAGION FROM A PRE-EXISTING CASE; OR MAY IT ARISE, DE NOVO, FROM FILTH-FERMENTATION?

He admitted that typhoid fever was caused by a micro-organism, but when the question was asked, Did it always arise from a pre-existing case, we were met by doubts and questions. That it had often arisen from previous cases could readily be proven; but it was difficult to prove that it was always so caused. There were but very few cases on record in which the disease had developed in such isolated surroundings as seemingly to preclude the possibility of contagion from another case; and in none, he thought, had the proof been altogether beyond question. He was willing to admit the possibility of its arising *de novo* from filth-fermentation, but he could not admit that this was more than a possibility.

Dr. Hermann M. Biggs, of New York, discussed the third question,

WHAT PART IS PLAYED BY MICRO-ORGANIC FERMENTS IN THE CAUSATION OF ENTERIC FEVER?

He said that he had found in cases of typhoid fever a peculiar, short, thick bacillus in the spleen, mesenteric glands, Pyer's patches, and sometimes in the liver and kidneys. All attempts to produce typhoid fever in the lower animals have failed, although no other bacillus has been found in the internal organs of uncomplicated cases of this disease, and this peculiar bacillus has never been found in any other condition. This bacillus, as present in the stools of typhoid-fever patients, has been found, in a few instances, in the water which has been the source of the disease.

D. E. Salmon, D.V.S., of Washington, discussed the fourth question,

IS THERE A DISEASE OF THE LOWER ANIMALS TRANSMISSIBLE TO MAN AS TYPHOID FEVER?

The speaker said that all his observations were made upon the lower animals, and were necessarily of a one-sided character, for he rarely saw cases of typhoid and other infectious diseases in man. No facts had ever come under his observation to lead him to believe that there is a specific disease in animals which produces in man a specific disease characterized by the presence of the bacillus of typhoid fever. The bacillus of hog cholera seemed to be identical with the bacillus just described as peculiar to the typhoid fever of man, both in its microscopical appearances and in its ability to live and be reproduced in drinking water. But in spite of the frequency of hog cholera in this country, no facts had come to his knowledge to show that it had produced a specific disease in man. He hoped that in the future we should be able to isolate the different ptomaines produced during the growth of the specific virus of the different contagious diseases, and, by using these, be able to produce a degree of immunity equal to that produced by one attack of the disease.

He thought that for the good of science there ought to be more sympathy of work between those who made a study of the diseases of man and those who studied the diseases of animals.

Dr. Charles A. Leale, of New York City, discussed the fifth question,

WHAT MEDIA OF CAUSATION OR TRANSMISSION OF TYPHOID FEVER ARE TO BE GUARDED AGAINST IN PUBLIC OR PRIVATE SANITATION?

He called attention to the importance of the disposal of sewage on garden-farms, and referred to the work done in this line by Dr. Carpenter. He expressed sympathy for the overworked hospital interne, who was peculiarly disposed to contract typhoid fever when exposed to the poison.

Dr. Everard D. Ferguson, of Rensselaer County, discussed the same point, and sketched the history of two epidemics of the disease in Troy. In the first epidemic the disease was traced to the water-supply from wells which tapped a superficial underground basin. In the second the source of the fever was thought to be in both the water and the air at the time of an overflow.

Dr. Charles G. Stockton, of Erie County, discussed the seventh question,

WHAT ARE THE INDICATIONS FOR TREATMENT; AND ARE RELAPSES OR UNTOWARD COMPLICATIONS FAVORED BY SOME ANTIPYRETIC MEASURES?

He said that the diet was a matter of the greatest importance; and as only a limited amount of food could be assimilated, it should be peptonized in order to bring it to the most easily digested form. Although he believed that the injurious effects of antipyrin and similar drugs were doubtless often due to their abuse rather than to the fact that they were contraindicated, yet he preferred cold sponging to reduce the temperature. The hygienic surroundings were most important—an airy, sunny, quiet room, a large single bed, and a good nurse were of prime importance.

(To be continued.)

AND INTRAVAGINAL DRAINAGE.

He described a new instrument, devised by himself, by means of which the urine passing through a vesico-vaginal fistula could be conducted directly to the receiving vessel, thus avoiding irritation of the vaginal mucous membrane. By means of this instrument he had been able to pass a rubber catheter up through the ureter into

with what facility the alcohol dissolves the diphtheritic exudation in the throat, lowers the temperature, and calms the pulse, showing its destructive action upon the germs of the disease, which have been absorbed by the glands and gained access to the blood. This remedy has been used by us in the treatment of diphtheria since 1873, during which time no case of the disease has slipped through our hands except in one solitary instance, and that case was in *articulo mortis* before the remedy was given. The remedy is also prophylactic to the disease, as we have found in many instances where it has not been expedient to quarantine the patient. For this purpose, it is only necessary for exposed persons to use the remedy, diluted as above stated, as a gargle and to swallow a little of it three or four times a day.—*Ed. N. Y. Medical Times.*

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 26, 1887.

F. R. S. DRAKE, M.D., VICE-PRESIDENT, IN THE CHAIR.

THE following nominations were made for

OFFICERS FOR THE ENSUING YEAR:

For President—Drs. Orlando B. Douglas,[1] Laurence Johnson, and Andrew H. Smith; *For Vice-President*—Dr. L. Bolton Bangs; *For Secretary*—Dr. Wesley M. Carpenter; *For Assistant Secretary*—Dr. Charles H. Avery; *For Treasurer*—Drs. Wendell C. Phillips and Alexander S. Hunter; *For Censors* (five to be elected)—Drs. R. Van Santvoord, John S. Warren, William E. Bullard, Daniel Lewis, Laurence Johnson, and William Stevens.

DR. J. OSCROFT TANSLEY then read a paper on

NASAL DIFFICULTIES IN EAR DISEASES,

in which he spoke of polypi, deviation of the septum, hypertrophy of the pharyngeal tonsil, post-nasal hypertrophies, bands seemingly cicatricial, atrophic or cicatricial rhinitis, simple secretive catarrh, adenoid growth in the pharynx, etc.

DR. O. D. POMEROY, in discussing the paper, spoke of the importance of treatment of the naso-pharynx in ear affections, of otitis produced by efforts to cleanse the nostrils by blowing the nose, of the deleterious effect produced by a too patulous opening of the Eustachian tube, and of the absence of stricture of the tube according to his observation.

DR. O. B. DOUGLAS spoke of the effect of stoppage of the middle and upper passages through the nose.

DR. WEBSTER had succeeded in treating the acute and subacute cases of otitis media without much reference to the naso-pharynx. He mentioned that he saw Politzer, during the last summer, treat two cases of what he called stricture of the Eustachian tube by means of bougies; he also saw him inject *warm* fluid into the middle ear, with the statement that it did no harm. He had not seen ear disease produced by adenoid growths in the naso-pharynx.

DR. A. S. HUNTER spoke of the effect of cocaine in restraining hemorrhage in nasal operations.

DR. TANSLEY said that he had plugged the nostrils much more frequently for the arrest of hemorrhage after the use of cocaine than before that drug came into use. He had not seen stricture of the Eustachian tube, and would not dare pass a probe into it for purposes of dilatation.

DR. D. M. CAMMANN then read a paper (see p. 476) on

TEREBENE IN DISEASES OF THE LUNGS,

in which he gave his experience in the use of this remedy in emphysema, bronchitis, and phthisis. The general result of his observations was that terebene is a valuable remedy in these affections. He had given it in doses of ten to fifteen drops three or four times a day.

DR. DOUGLAS spoke of the good effect produced by the use of terebene in tubercular laryngitis.

DR. WALLIAN thought that if the influence of the drug was due to the peroxide of hydrogen set free, larger doses might be used with advantage.

The discussion was continued by Drs. Wesley M. Carpenter and John C. Peters, after which the Society adjourned.

VICARIOUS MENSTRUATION THROUGH THE EAR.—A young woman on board a steamer coming from Algiers suddenly felt blood flowing from her ear without having previously felt ill. About a tumblerful escaped. Careful examination of the middle ear disclosed nothing abnormal. A day or two subsequently menstruation took place by the natural channel, and nothing further occurred. In commenting on the fact, Dr. Pirondi states that of the 200 cases of supplementary hemorrhage cited by Puech only 6 came from the ear.

[1] Since declined.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, April 27, 1887.

A SUBSTITUTE FOR THE ORTHODOX PESSARY—DISCUSSION OF DR. WYLIE'S PAPER (see p. 483).

THE subject being open for discussion,

PROFESSOR ISAAC E. TAYLOR said: "I am pleased to hear Dr. Wylie speak as he does against the pessary. It is very seldom I resort to it. I do not think that I have used the Hodge pessary more than two or three times. There is a very important remedy which was employed as far back as 1843, viz., bichloride of mercury. I have seen patients benefited largely by its use. For some time I have used the formula which Dr. Wylie recommends."

DR. J. H. FRUITNIGHT said: "It will be conceded by all that the pessary does not come up to expectation. I do not think that in itself it should be considered as a curative agent. I regard it merely as an auxiliary. Most of the cases of uterine displacement are attended by more or less physical debility, and I think that constitutional treatment has a great deal to do with their cure.

"In cases of simple prolapsus, for instance, the general building up of the system is quite as essential as the use of the pessary; and yet, in those cases, I would not discard the pessary, because one supplements the other.

"I have been in the habit of using the tampon saturated with glycerine and alum, in the way suggested by Dr. Wylie, and have seen cases of subinvolution of three to six months' standing benefited by this treatment."

DR. W. M. MCLAURY said: "Several years ago I was in the habit of using something in that way; but latterly I have used simple tar applied to a compress of cotton, in the same way as Dr. Wylie has mentioned, and with the happiest results."

DR. M. BLUMENTHAL said: "In a practice of about thirty-five years, I have not used the mechanical pessaries, which were so much in vogue some years ago, more than a dozen times, because they did not commend themselves to my judgment. I believe they did as much harm as good. At first I used small sponges, and as the sponge absorbed the fluid, it spread and exerted considerable force in sustaining the uterus. For the past fifteen or sixteen years I have not used sponge, but, instead, a cotton tampon with a solution of glycerine. My experience with it has been very satisfactory, while with the mechanical pessary it has been quite the reverse. The incidental fact alluded to by Dr. Wylie, of the abstraction of congesting fluids from the diseased organ, is an important one. While the cotton tampon supports the organ, it also relieves it of the excessive weight; and, in conjunction with warm water and rest, it commends itself as being the best treatment."

DR. C. S. WOOD said: "I have used pessaries in some cases with satisfactory results, but am much less in favor of them than I was years ago. I would like to have heard from Dr. Wylie regarding the effect of his application in cases of laceration of the cervix. I have been in the habit of using tampons with glycerine and tannin, and have often allowed them to rest for three days without any resultant trouble. By keeping up the use of these tampons for a certain length of time in connection with hot water, I have found that although these lacerations were not closed, yet they were so nearly well that they gave the woman no further trouble; and she could go on for years, perhaps, without any special difficulty."

DR. A. M. JACOBUS said: "The exposition given by Dr. Wylie of his treatment has been unusually clear, and, having been more or less associated with him, I have been much pleased to hear it presented so well. I would like, however, to mention a point in connection with boro-glyceride: There are many patients who cannot bear glycerine. If each gentleman will touch his finger to this boro-glyceride, and then to the glycerine itself, he will feel the difference. The boro-glyceride is smooth,

like oil, and the other is keen and sharp. I think it must have the same feeling in the vagina. It is my opinion that almost all displacements are due to new-growths or inflammatory disease, and if the disease is cured the pessary will not be needed. I have found that wads of cotton are very distressing to some women, even if applied light and loose. I have not yet tried the antiseptic sheep's wool as suggested recently, but presume that it is much more elastic than cotton, and that it might take its place to a large extent. The question is whether wool would be more irritating than cotton, on account of its peculiar formation.

"With reference to alum, I have found that with many of my patients it could not be used, and I therefore keep the alum in a separate solution, so that it can be used only when practicable.

"Glycerine is far preferable to hot water. As employed in private practice hot water is of no use, except that it cleanses the vagina. Warm water with a little borax in it will answer just as well; then let the woman use the glycerine tampons. In simple displacement the patient should assume the knee-chest position daily for about five or ten minutes, and if she would then lie upon her stomach for half an hour, I think it would do much to relieve the pelvic distress.

"In the treatment of erosions of the cervix, calomel is as good a remedy as iodoform, which smells badly and is very disagreeable to patients. I have seen cases, which would not yield to tincture of iron, iodine, nitrate of silver, or iodoform, yield quickly to calomel dusted on freely."

Dr. E. S. Peck observed that glyceride and alum had been successfully introduced into ophthalmological practice as a disinfectant and astringent. Glycerine has long been in use as a detergent in collyria. It happens occasionally, however, that a patient shows an idiosyncrasy against the local use of glycerine in conjunctival diseases.

Dr. P. C. Cole said: "I have been much pleased with the statements made by Dr. Wylie. I have not been in the habit of using the pessary to any great extent. Some years ago my attention was drawn to the use of cotton pessaries in a systematic manner, and since that time I have employed them with a great deal of pleasure to myself and comfort to my patients. I have never used the special preparation of boro-glyceride and alum, but almost any of the preparations which are in ordinary use are good. I have never dared to leave a tampon in longer than twenty-four hours."

Dr. Henry L. Taylor said: "I would like to call the attention of the Society to the fact that general practitioners, and even specialists, in female diseases must meet with a great many cases where local treatment is not altogether successful. I often see cases of that kind which are ordinarily classed as uterine, or semi uterine; many of them having been through many hands and subjected to a great variety of treatment. In such cases I find special benefit in the use of a general hygienic plan in which systematic exercises play a considerable part. I have generally observed that, in such cases, the interest of the surgeons seems to be localized, and the patients treated more particularly in regard to the generative apparatus than as persons, and if the speculum revealed an improved condition the case was considered to be satisfactory; whereas little interest was displayed in following up the cases for a considerable time afterward, in order to observe whether the symptoms of which the patient complained had really disappeared. The symptoms would often come back, and, as a matter of fact, I know many who submitted to treatment for uterine displacements, and were not cured of the symptoms of which they complained. It is just that class of cases which is so successfully treated by a systematic plan of general hygienic exercises."

In closing the discussion Dr. Wylie said: "In bringing this tampon forward I do not claim that its main object is the holding of the uterus in position. It is really the action of the remedies upon the circulation of the pelvis which is so beneficial. Ordinarily, if you procure this mixture in a drug store, you will get something which will disappoint you. This is boro-glyceride, and not boro-glycerine. It is the presence of the boro-glyceride in the mixture which enables the cotton tampon to be retained in the vagina for so long a time. Impure glycerine is very irritating, but pure glycerine is not. If I find that alum is too astringent, I often use as a substitute acetate of aluminum. I do not know that boro-glyceride has any irritating qualities at all, but it is a very powerful antiseptic. I could not successfully treat a good many cases that come to me except by this simple means. It improves all conditions of the pelvis where there is congestion."

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PAST AND PRESENT STUDENTS OF MEDICINE—ATHLETICS—POST-GRADUATE CLASSES—SPECIAL TEACHING—SOME RECENT DEATHS—MR. QUAIN, F.R.S.—MR. BLOWER—DR. CUMING—DR. BARR MITCHELL.

London, September 20, 1887.

With the near approach of the winter session all the complicated machinery of medical education is being set in order again, and will soon once more be working at full speed. Nor does the annual throng of those who seek to join our ranks suffer any diminution in spite of the increased difficulties in their path. The increased and increasing complexity of medical studies, combined with augmented stringency of examinations, have rendered the career of a medical student much more thorny. He has to work now—not spasmodically, for a few months before each examination, but regularly, throughout his allotted term of study, if he wishes to succeed. He has also to pay more dearly for his privileges. Within the last few years most of the medical schools have raised their fees, and the conjoined scheme of examination is also accompanied by increased examination fees. Yet medicine is as popular a profession as ever—perhaps more so. Although not yet accorded the position to which it is entitled, it can scarcely be denied that medicine, as a vocation, now occupies a higher position in public esteem than it did a generation ago. The social position of its practitioners has also distinctly improved, though pecuniarily the average doctor has unfortunately not advanced much. A more enlightened public now recognize more generally the claims of the profession, and to this the great stride taken by preventive medicine has materially contributed. Within the last few decades the type of medical student has undergone considerable evolutionary changes. These can easily be perceived even by those who can cast their memory back only ten or fifteen years. Those who can mentally retrace their steps for some thirty years see still more clearly the change for the better which has come over the youthful disciples of Æsculapius. The medical student of to-day is not the beer-loving, pipe-smoking, knocker-wrenching individual of by-gone days, and bears but scant resemblance to the delineations of his class to be found in the pages of Dickens. We do not now find a circle of smokers round the dissecting-room fire with a poker kept red-hot wherewith to light pipes, nor does the beer-can travel to and from the nearest tavern. Many students are both non-smokers and total abstainers, and to be one of the latter is now no longer a mark of reproach. Yet although the present-day student is usually quiet in demeanor and of gentlemanly habits, he is not by any means a milksop. Athletics flourish as vigorously as

ever among students of medicine, and a cricket or football match will draw a large audience, including very frequently many members of the staff. Indeed, many still go in freely for athletic sports even after entry upon the cares and toils of actual practice. England's chief cricketer, W. G. Grace, is a medical man, and his brother, Edward Mills Grace, of equal renown with the bat, is also in actual practice. Cycling counts many adherents from among us, among whom I may specially mention Dr. B. W. Richardson, F.R.S., who is an enthusiast on the subject, and does his best to recommend it both by personal practice and earnest advocacy by tongue and pen.

While so much is being done for the embryo practitioner, comparatively little is being done for the higher education of those already qualified. A post-graduate course was held last session at one of the metropolitan medical schools, and was moderately successful. One is announced for the coming session at another hospital (Charing Cross), and the smallness of the fees (two guineas inclusive) ought to prove an attraction. For those interested in bacteriology, some special courses are announced at King's College, under the direction of Professor Crookshank, who is untiring in his devotion to the subject. The arrangements made for systematic and practical instruction in the subject seem very complete.

At Edinburgh, Dr. Hunter Mackenzie commences today a post-graduate course in laryngology and rhinology, at the Eye, Ear, and Throat Hospital, but it is "a far cry" from the banks of the Thames to "Auld Reekie." At a few of the special hospitals teaching is made a feature. It is probably carried out most thoroughly and extensively at the Royal Ophthalmic Hospital, Moorfields. The chief drawback is that it is not sufficiently elementary, but only adapted to students who have made some progress and have had some practice with the ophthalmoscope. Those who have already obtained some proficiency in ophthalmology may learn a great deal. The hospital contains one hundred beds, and in the course of a year twenty-five thousand patients attend the out-patient department. The active staff consists of one physician, five surgeons, and four assistant surgeons—all of them willing and eager to teach.

Several medical men of note have recently passed to their rest. Foremost among these I must name Mr. Richard Quain, F.R.S., the eminent surgeon, who died on Thursday last. He must not be confounded with Dr. Richard Quain, the learned editor of "Quain's Dictionary of Medicine," who is also a Fellow of the Royal Society (F.R.S.), but is still living. Mr. Quain was for many years surgeon to University College Hospital, and at the time of his death was Surgeon Extraordinary to the Queen. He had served the office of President of the Royal College of Surgeons, and formerly represented that body in the General Medical Council. He was the author of several works. His elaborate work on "The Anatomy of the Arteries of the Human Body, with Its Applications to Pathology and Operative Surgery," is generally regarded as his chief work. It consists of an atlas (quarto), with an accompanying letter-press of commentary. His mental activity was undiminished, even in extreme old age; and three years ago, at the patriarchal age of eighty-four, he published a handsome volume of clinical lectures, sumptuously illustrated by forty plates, many of them being beautifully colored, and giving very faithful portraitures of various diseased conditions. Mr. Quain was very tenacious about the proper style of address, and to anyone who addressed him orally as "Dr.," instead of "Mr.," he would testily reply: "Don't call me Doctor, sir; I'm not Doctor."

Two other octogenarians have also lately quitted our ranks. The death of Mr. William Blower, at Bedford, after an illness of twenty-eight years, will be marked with regret by many. The name of Blower has been medically associated with the city of Bedford for nearly a century, and Mr. William Blower himself practised there upward of thirty years. In the sister isle Dr. Thomas Cuming, of Armagh, lately departed at the advanced age of eighty-nine years, sixty-seven of which had been spent in practice.

Another death of note is that of Dr. Barr Mitchell, which recently occurred. A man of much education and culture, he had visited many lands, and was interested in many. History was one of his favorite studies. Among his scientific pursuits, that of disinfectants occupied a prominent place, and he was for some years associated with Mr. Bollmann Condy in business in connection with Condy's Fluid. At the time of his death he was much interested in the question of salmon culture. He was not in practice.

OUR PARIS LETTER.

(From our Special Correspondent.)

DR. NACHTEL, AND THE AMERICAN SYSTEM OF AMBULANCES—THERAPEUTIC PROPERTIES OF ANTIPYRIN—LEFT-HANDEDNESS AND RIGHT-HANDEDNESS—ANTISEPTIC PRECAUTIONS IN DUELLING.

PARIS, September 23, 1887.

It is now more than six years since Dr. Henri Nachtel endeavored to introduce the American system of ambulance for cases of accidents in the streets of Paris. This fact has more than once been brought to the notice of your readers; and if I refer to it again, it is to inform you of the complete deception our confrère has met with regarding his project, which, after having been most favorably entertained, and almost adopted, has been set aside, and another organized in its stead under the auspices of the Prefect of Police. After this long period of bureaucratic procrastination, during which time Dr. Nachtel was buoyed up with hopes that his project would be realized, and after having sacrificed his time and personal interests for the cause he had so much at heart, he received an official notification that "his quality of a foreigner interdicted the French functionaries from concluding any affair with him." As above noted, that a French ambulance has been introduced, which, if not the exact copy of Dr. Nachtel's conveyance, he unquestionably deserves the credit of having given the French authorities the idea of providing for such a long-crying desideratum in their country.

About the beginning of August, Professor Germain Sée made a communication to the Academy of Sciences on the therapeutic properties of antipyrin, and about a fortnight ago he read a paper before the Academy of Medicine on the same subject. In this paper he treated of the various therapeutic applications of this new drug. He thinks he has found in antipyrin a medicament of great therapeutic value, and it may be considered a panacea for almost all affections that the human being is subject to—not that it possesses a curative power in all diseases, but for the relief of that most important element, pain, it is unequalled, in which respect it resembles opium, but it has none of the inconveniences of the latter. The learned professor employs it in all cases where pain is the predominant symptom, whether this be attended with or without fever, though he has found it more applicable to apyretic cases. It is true that when antipyrin was discovered it was freely used for lowering the temperature in fevers, but it does so in so sudden a manner that Professor Sée thinks that this result cannot be produced without danger to the patient. He has found it most useful in cephalalgia, megrim, and facial neuralgia; also in gout, rheumatism, sciatica, tabetic pains, hepatic colic, nephritic colic, dysmenorrhœa, cardiac pains, angina pectoris without sclerosis and without ossification of the coronary arteries. For rheumatism, however, it is only when the heart is affected that Professor Sée employs antipyrin, but in all other cases of this affection accompanied with fever he still gives the preference to the salicylate of soda.

In localized rheumatism, in apyretic rheumatism, in hydrarthrosis, antipyrin has proved most efficacious. Antifebrin produces almost analogous results, but it is a dangerous remedy; and although it has a curative effect in the above cases, yet from its toxic influence it should be discarded—the patients become blue, the oxyhæmoglobin of the blood is transformed into metahæmoglobin, and the respiratory faculty of this liquid is arrested. There is, therefore, no advantage in subjecting the patient to such dangers; whereas antipyrin, which gives the same therapeutic results as antifebrin, is, moreover, absolutely inoffensive.

As for salol, it is very inferior to all the preceding drugs, and particularly to the salicylate of soda. It is now much less employed internally, and it is only used in surgical cases on account of its antiseptic properties. Professor Sée administers antipyrin by the stomach and by hypodermatic injections. In the former case it is given in doses of from thirty to fifty centigrammes, to the extent of two or three grammes per day. In injections he employed, at first, a solution of fifty centigrammes of antipyrin to the same quantity of water, but finding that these injections caused pain, he added one centigramme of cocaine to each injection, or in some cases he only increased the quantity of water to one and a half gramme.

In the "Journal des Connaissances Médicales," Dr. Galippe studies the subject of left-handedness and right-handedness, as to whether these conditions are the results of education or of heredity. As Dr. Galippe has a predilection for dentistry, he naturally prosecuted his researches in that direction, and based the results principally on dental anomalies. Thus, of 64 cases of these anomalies observed by him, allowing abstraction of the numerous cases in which the anomalies were symmetrical, he found 41 anomalies on the left side, and 23 on the right; and even here 3 cases of the right should be deducted, as they happened to be left-handed. The works of other investigators show the same frequency as regards anomalies of the left side. In a work by Dr. Magitot, he has shown that anomalies of form and direction are more frequent on the left side than on the right. Dr. Gaillard, writing in 1881, stated that the frequency of anomalies was twice as great on the left side as on the right. The canine teeth would perhaps form an exception in a heterotopic point of view. From what precedes, the deduction is that in right-handed persons the left maxillary constitutes a seat of election for the anomalies, whereas in the left-handed it is the right maxillary which presents this particularity. Left-handed persons are relatively rare. According to Delaunay, there is one in forty individuals; according to Galippe, they belong to the degenerate class. They are frequently the subjects of nervous heredity.

A great many epileptics are left-handed. Of 363 lunatics (males), 4.13 per cent. were found to be left-handed; and of 117 female lunatics, 4.27 per cent. were left-handed. On the other hand, as regards sensibility, Drs. Amadeï and Tonini have found, of 90 lunatics, 73 individuals in whom sensibility was more marked on the left than on the right side. Moreover, according to Marro, it is found that among criminals there are three times more left-handed persons than among those who have not committed any crime or misdemeanor. From these researches Dr. Galippe concludes that left-handedness is not particularly due to habit or education; it is more rational to suppose that we are right-handed by atavism, and left-handed by morbid heredity.

If duels are not often fatal to the combatants in France, it is said to be due to the adoption of pre-antiseptic measures. In a recent duel between two French literary characters, in which both the combatants were wounded, their wounds healed up in a very short time. This happy and prompt result was attributable, not only in a great measure to the youthful age of the combatants, but to the precautionary measure taken in dipping the swords in a solution of carbolic acid. This idea was imported into France by Dr. Pozzi, a well-known Parisian surgeon, who attended a duel about two years ago in Hungary, where he had seen for the first time that the swords used for the occasion were smeared over with carbolated oil. It would appear that this practice has since been in usage in France, but the French are rather piqued at the idea of its having originated in Germany.

HIGH FEES IN VENEREAL DISEASE.

To the Editor of The Medical Record.

Sir: Referring to Dr. P. L. Myers' inquiry as to why we should take a retainer in venereal disease, I would respectfully submit that *I* take a retainer in these cases because experience has taught me that, in these cases, if I don't take my pay in advance I am not likely to get it at all. My reasons for asking a higher fee than in non-venereal cases is, that the diseases are usually disgusting in their nature, and always communicable, so that the physician runs a risk of inoculation and ought to be paid in proportion to his risk; and, besides, if a man can find funds to pay for *getting* these diseases, he can find funds to pay for getting rid of them. Yours truly,

Geo. E. Blackham, M.D.

Dunkirk, N. Y.

THE HEALTHFULNESS OF CONTINENCE.

To the Editor of The Medical Record.

Sir: In your comments on the fee for treating venereal diseases, you say, or imply, that sexual desire should be controlled much as if it were an appetite for something injurious. Is it not true, with some exceptions perhaps, but still as a rule, that if a man, from his youth up, refrain entirely from having sexual intercourse, he will have emissions from time to time, at first with lascivious dreams, but after the lapse of years insensibly; that his testicles will become gradually flattened, and that, sooner or later, probably in middle life, he will find himself incurably impotent? Is it not also true that the second change of life comes quickly to virgins, frequently before their thirtieth year; and that few men or women go without coition and reach middle life perfectly robust and well?

Many physicians, perhaps from lack of physiological information, are inclined to treat the subject of sexual intercourse solely from a moral point of view. But this is exactly the view which, professionally, does not concern them. We go to physicians, not for spiritual advice, but for science. If it be better for us physically to have coition regularly, say once or twice a week, than to go without such indulgence, it seems to me that the physicians to whom we pay our money are in honor bound to tell us so.

S. B.

New York, August 23, 1887.

[I. It is not true, as a rule, that men who are continent till middle age are then incurably impotent.

II. It is not true that the climacteric comes to virgins frequently before their thirtieth year.

III. On the whole, spinsters are as healthy a class as the married women of to-day.

IV. There is a difference between what is necessary for health and what is simply the best. The physician takes an enormous responsibility in advising fornication, and there is justly a strong feeling against it among the great majority and the better class of the profession.—Ed.].

New York College of Veterinary Surgeons.—Dr. Frank Grauer delivered the introductory lecture to the students of this institution on Thursday evening, September 29th.

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 32, No. 16. NEW YORK, OCTOBER 15, 1887 Whole No. 884

Original Articles.

AN APPRECIATION OF THE MODERN METHOD OF TREATING SYPHILIS BY HYPODERMIC INJECTIONS.[1]

BY PRINCE A. MORROW, M.D.,

CLINICAL PROFESSOR OF VENEREAL DISEASES, IN THE UNIVERSITY OF THE CITY OF NEW YORK.

AMONG the notable papers presented at the last meeting of the British Medical Association, the most remarkable was the "Address in Medicine," by Professor Gairdner, in which he undertook to answer the somewhat cynical question of Sir William Hamilton, "Has the *practice* of medicine, that is, the art as distinguished from the science, made a single step since the days of Hippocrates?" In his comprehensive and scholarly survey of the field of modern medicine, the distinguished orator found many signs of progress, and indicated numerous diseases in which the methods of medical practice had been entirely revolutionized, and placed on a simpler, sounder and more scientific basis.

With reference to one department of practical medicine, however, the treatment of syphilis, the question may be very pertinently asked, "are we better than our fathers?" in other words, is the treatment of the present day a material advancement over that practiced four hundred years ago? Certainly, with respect to the means employed for the cure of the disease, the answer must be in the negative. While our therapeutical resources against the later manifestations of syphilis have been supplemented by the addition of one important adjuvant, iodide of potassium, mercury still remains, as it was then, the basis of all special curative treatment. The treatment of syphilis in the nineteenth century differs from that employed in the fifteenth in modification of method and detail rather than in essential nature.

This fact constitutes the reproach as well as the boast of syphilography. The reproach, because while immense advances have been made in our knowledge of the natural history of syphilis; of its varied, complex, and far-reaching etiological and pathological relationships, science has discovered no remedy superior, or even equal in efficacy to that employed in 1495.

But, on the other hand, if *stability* be recognized as the true test of the value of a treatment, then may the specialist, with perfect propriety, boast that the very permanence of mercurial treatment, stamped as it is with the seal of professional approval after four centuries' experience, constitutes the highest testimonial, as well as the positive proof of its superior value.

While mercury still maintains its supremacy as the sovereign remedy in syphilis, the traditional methods of its therapeutic application have been essentially modified, and the principles of treatment established on a more rational and scientific basis. With a clearer appreciation of what may be accomplished by specific medication we have also learned to recognize its limitations. We no longer attempt to expel the syphilitic virus from the recesses of the economy by therapeutic violence; on the contrary, we regard any treatment which seriously disturbs the physiological functions as positively pernicious.

[1] Read before the New York Academy of Medicine, October 6, 1887.

The genius of modern mercurial medication is in the direction of *attenuation;* instead of overwhelming the syphilitic diathesis with a metallic mass, the treatment has been drawn out, or extended, to correspond to the natural life term of the malady.

Professional opinion, based upon large experience and observation, seems to have settled down to the conviction that the therapeutic specificity of mercury in syphilis is best developed by its administration in small doses during a long period. However efficient mercury may be in syphilis, its most ardent and enthusiastic advocate would hardly contend that it fulfils all the conditions of a perfect remedial agent. To say nothing of the merited disrepute into which it has fallen from time to time on account of its abuses, even its most judicious employment is often attended with inconvenient and ill effects.

A multitude of agents drawn from both the mineral and vegetable kingdoms have been brought forward as succedaneums, but, after a more or less ephemeral notoriety, they have fallen into disuse. The investigations of recent years have not been directed to the development of new therapeutical agents, but rather to improvements in the methods of administering mercury, with the view of obviating its disadvantages while availing ourselves of its incontestable efficacy.

The hypodermic employment of mercury constitutes the most recent innovation upon the older and classic modes of introducing this drug into the system. It may be properly designated a modern method of treating syphilis, since its introduction dates back but little over twenty years. The term does not necessarily imply a new means of cure. With our present knowledge of the agents best adapted to combat the disease, mercury forms the backbone of every system or method of treatment.

It is not merely novel in the method of mercurialization it proposes, but if the claims of its more enthusiastic advocates be substantiated, it revolutionizes the principles of treatment. It not only exalts mercury to the rank of a specific antidote to the syphilitic virus, energizing its action, and widening the range of its specific influence so as to include the lesions of the tertiary stage, but it overturns the general belief in the necessity of a continuous and prolonged treatment, and singularly modifies the prevailing conception of the quantity of the drug required to effect a cure.

A priori and from a theoretical point of view, the hypodermic method has much to commend it to favor. Certain advantages are obvious. It combines accuracy and precision of dose with greater rapidity of action and increased effect from a minimum quantity. It is not so liable to produce stomatitis and gastro-intestinal disorders, as when the drug is given by the stomach. Compared with the dermic method with which it has most analogies, the inunction treatment is inaccurate, unscientific, and uncleanly, prone to produce ptyalism, liable to determine dermatitis of various degrees of intensity, which often compels its suspension. Certain claims which may be considered as yet *sub judice*, are that the hypodermic use of mercury increases its potentiality, enabling it to triumph over refractory lesions which resist ordinary methods of treatment, and that its action is more permanent, as shown by the comparative infrequency of relapses.

If these claims could be verified and the process be freed from certain disadvantages and ill effects which

have thus far proved inseparable from its use, the modern method would represent the ideal treatment of syphilis.

The subject of the hypodermic treatment of syphilis has for a long time engaged the earnest attention of the profession abroad. Its relative advantages and disadvantages, compared with the older methods, have been the theme of the liveliest discussions before learned societies and through the medical press. I have thought the subject of sufficient interest and importance to bring before this Academy with the view of eliciting the experience and views of our own specialists as to its therapeutic worth.

My personal experience with this method has been comparatively limited. During the past summer, however, circumstances favored me with an opportunity of studying the results of hypodermic medication on a large scale in the male and female Syphilitic Hospitals of Paris—the Loureine and the Du Midi—of witnessing its effects both upon the disease and upon the patients—of freely discussing its merits and demerits with the operators, so that my observations have somewhat of the value of personally conducted experiments.

Before attempting a critical appreciation of the true value of the hypodermic treatment of syphilis, it may be well to indicate its present status in professional confidence, and give a brief resumé of its history.

This method, after passing through the vicissitudes common to any departure from traditional practice; after being extolled and adopted by leading authorities, condemned and rejected by others, it has made of late years decided progress in professional favor in Italy, Germany, Sweden, Finland, Russia, and France. In England it has been experimented with to a limited extent, but has not made any headway. In this country it has not been largely employed, and with results so unfavorable that of late years it has been practically disregarded as a means of cure.

It is not my purpose to give a complete history of the hypodermic method, or even a complete list of all the compounds of mercury which have been tried subcutaneously. The refinements of the chemists' art have been brought into requisition in order to provide preparations which should combine facility of absorption with freedom from irritation: Amides, chlorides, cyanides, iodides, oxides, chromates, nitrates, sulphates, and even metallic mercury have been experimented with, but most of these have fallen into disuse.

At the present time, the bichloride, the formamide and the ammoni-peptonate, representing the group of soluble salts, and calomel and the yellow oxide, the insoluble salts, are most generally employed.

The former are introduced in a soluble state and in a condition favorable for immediate absorption; the latter are injected in the insoluble state, and, by a process of slow chemical reaction, are rendered soluble and gradually absorbed. The supply of the former must be frequently renewed once or twice a day, on account of the rapidity of its absorption and elimination, which is ordinarily effected within twenty-four hours. The latter is introduced in a relatively small quantity, and at long intervals; its slow absorption and elimination insuring an impregnation of the system during a long period. Traces of the mercury thus introduced, it is claimed, may be found in the saliva and urine after the lapse of six months to a year, and even longer. Although there has been a synchronous development of these two procedures, it will be seen that they are essentially distinct in the mode of mercurialization, and it will be convenient to consider them separately.

The honor, by some considered doubtful, of introducing the bichloride into the system subcutaneously belongs to Hunter and Hebra. Their experiments were so unsatisfactory that they were soon abandoned, and the results never published.

Later, Lewin reviewed the use of the sublimate injections, and his results, published in 1867, gave a fresh impetus to the prosecution of experiments in this direction. He used a solution of the salt in distilled water, the quantity injected each time representing about one-eighth to one-sixth grain of the bichloride. He claimed remarkable results, but the pain and local accidents which were produced at the points of puncture constituted serious objections to its employment. These inconveniences were sought to be corrected by changes in the menstruum, and the addition of various agents, such as albumen, peptone, glycogoll, with a view of dulling the caustic edge of the sublimate salt. The ammonio-peptonate of mercury probably represents the least objectionable soluble preparation which has as yet been devised. M. Martineau assured me that he had used it in 6,000 cases of syphilis, making in all 200,000 injections, on an average about 30 to each patient, without a single accident. From my personal observation I can assert that it is by no means painless, as has been claimed. The lateral posterior parts of the back are chosen as the seat of the injections. A fold is pinched up and the needle plunged obliquely to its full length. After it is withdrawn, friction is made over the surface with the view of facilitating absorption. One injection, representing 10 milligrams, is made each day.

The pain, eschars, and abscesses, formerly quite frequent, have been much diminished by improvements which have been made in the preparation used, the technique of its application, and the seat of the injections. Jullien, the distinguished Lyons authority, declares that he has used sublimate injections in thousands of cases, without a single accident. He plunges the needle in the muscles of the buttocks. As indicating the comparative rarity of inflammatory accidents, Smet gives the following statistics.

Lewin used 300,000 injections with only 20 abscesses; Paikert, 5,000 injections, without accident; Sigmund treated 631 patients with only 5 abscesses; Smet, 900 patients without any local accident whatever.

The average quantity of the bichloride requisite to effect a cure of syphilis is fixed as twenty-five to thirty centigrammes for males, a slightly less amount for females.

The hypodermic use of an insoluble salt of mercury in the treatment of syphilis, was introduced by Scarenzio, in 1864. He was led to employ calomel on the ground that it was less irritating to the tissues, and that it would be gradually converted into the bichloride by a chemical reaction with the alkaline chlorides of the system. He calculated that forty centigrammes of calomel represented the quantity of the bichloride requisite to effect a cure. This amount suspended in glycerine, for which he afterwards substituted mucilage, was injected in two different places, or at two different sittings. As the seat of the injections he chose the extremities and lateral sides of the chest. The effect of these upon the syphilis was most favorable, but in every instance an abscess formed at the seat of the injection. This result was for a long time regarded as an inseparable condition of the employment of calomel injections. His second series of experiments were more successful. By reducing the quantity of calomel introduced at each seance, and greater care in the technique of the operation, he obtained better results with fewer abscesses.

Scarenzio's method was taken up by numerous experimenters in Italy, Germany, and elsewhere, most all of whom attested its remarkable efficacy, but had to deplore its unfortunate concomitant in the shape of local accidents, which rendered its general use impossible.

In 1882, Smirnoff, who had experimented largely with Scarenzio's method, made certain modifications which largely reduced the proportion of abscesses. He found by injecting small quantities of calomel into various parts of the trunk and extremities, that in all cases he produced abscesses which either opened or had to be incised; the other points of injections were tumefied half the size of an egg, sensitive and painful. He injected much larger quantities of calomel in each buttock with the re-

sult that abscesses occurred much less frequently, and the inflammatory reaction was less painful and severe.

The method of Scarenzio as modified by Smirnoff, consists in the injection of ten centigrams of calomel in the buttock; this injection to be repeated two or three times at intervals of eight to fifteen days, according to the effect upon the symptoms.

Smirnoff asserts that this method constitutes the most simple, convenient, exact, and efficacious treatment of syphilis. It is well-supported by children and pregnant women, and is applicable to all stages of the disease. He gives statistics of one hundred and thirteen cases of tertiary syphilis treated exclusively by calomel injections, and in only sixteen were there relapses. He admits that relapses occasionally occur after this treatment in the secondary stage—usually upon the mucous membranes. All experimenters agree that the efficacy of injections is less marked in the case of mucous patches; here local treatment is necessary. He fixes the exact dosage of the amount of calomel necessary to cure syphilis when used hypodermically as follows: in the first years of infancy at twenty-four to thirty-six milligrammes: from fifteen to sixteen years about the same quantity as in adults. He computes that forty to fifty centigrammes, four or five injections, is sufficient for the complete cure of secondary syphilis including its relapses; while twenty to thirty centigrammes, two to three injections, represents the average dose necessary to cure the symptoms of tertiary syphilis. It would appear then, that the quantity of calomel required to effect a cure of syphilis at all ages and in all its stages, admitted of definite mathematical expression.

Within the past year injections of the insoluble compounds of mercury have been experimented with on a large scale in the Paris special hospitals, by Balzer at the Loucine, Du Castel at the Du Midi, and Besnier at the St. Louis. Balzer substituted the oil of vaseline for glycerine, as an excipient both for calomel and the yellow oxide of mercury. Great care is taken that the preparation of mercury should be perfectly pure. It is finely pulverized, washed in boiling alcohol, dried and suspended in the vaseline in the proportion of 1.50 grains of calomel to 15 grains of vaseline, 1 cubic centimetre of the fluid representing 10 centigrammes of the active agent; the yellow oxide is combined in the proportion of 10 centigrammes to 1 gramme of vaseline.

Balzer has the patient lying upon the face, the operator's hands are washed in an antiseptic liquid; the place of injection, in the central depression of the buttock, is wiped off with salicylated cotton, dipped in the antiseptic solution. The needle, which should be of large calibre, is introduced vertically downward into the subcutaneous tissues, and the fluid slowly forced out. The needle is withdrawn, pressure being made against it to prevent escape of the fluid along its track and the consequent formation of a canicular abscess, and the point of puncture antiseptically dressed. No massage or friction of the parts is practiced. The patient usually maintains the recumbent position three-quarters of an hour, and then goes around as usual. The operation is repeated in from eight to fifteen days, and the patient receives on an average four injections.

Smirnoff, whom I met in Paris, demonstrated to me his method of making the injections, which is slightly different. The point of the injection should be 3 centimetres behind the posterior border of the great trochanter, and the needle should be introduced horizontally into the subcutaneous tissues. If a second injection is to be made in the same buttock, it should be at least 3 centimetres above or below the first. When the injections are thus made he claims that even should intense inflammatory reaction supervene, there is no pressure upon the inflamed parts when the patient is sitting or lying down.

The immediate pain from the injection is trifling and almost nil. In a few days, generally within forty-eight hours, there is observed an inflammatory engorgement of the part, more or less extensive, and quite painful. It may attain the size of an egg or larger, and then gradually undergo involution in the course of ten or fifteen days, or the inflammatory reaction may proceed to suppuration. Resorption of the pus sometimes takes place, or the abscess may have to be opened. In his first series of experiments, comprising 107 injections, Balzer had 15 abscesses; in the second series of 84 injections, there were only 3 abscesses. He does not attach much importance to this complication, regarding it only as an inconvenience interfering with an early repetition of the injection.

An examination of a large number of statistics shows that there has been a progressive diminution in the occurrence of this complication. In Scarenzio's first series of cases it occurred in one hundred per cent. of the injections. Still later it was reduced to twenty-five per cent., and now it occurs only in a small proportion of cases, four to six or eight per cent.

The marked diminution in the frequency and inflammatory character of the local accidents is no doubt due to the greater care observed in the preparation of the injection, insuring its freedom from impurities, carefully cleansing the needle before introduction, so that the solution does not come in contact with the derma, and in the selection of the place of injection.

Besnier's practice is to carry the injection down into the muscular tissues. Abscesses and other local accidents, it has been observed, are incomparably more frequent in women than in men, and in fat than in lean persons generally. This may be explained by the greater thickness of the adipose covering in this region, and the relatively more superficial seat of the injection.

Although the tendency of the formation of abscesses has been in a great measure corrected by improvements in the technique of the operation, yet the inflammatory nodular induration seems to be an inevitable concomitant of calomel injections. The inflammatory reaction varies in extent and degree of severity, sometimes causing considerable swelling. In other cases the induration may be felt rather than seen, and is exceedingly sensitive and painful to the touch.

I had an opportunity of examining a number of these nodular masses which Balzer had removed from the buttocks of a patient who had died from phthisis. In each specimen, representing a small cellulo-adipose mass, there was a blackened foyer or centre of necrosed tissue. This necrotic process was supposed to be due to the intensity of the chemical reaction which occurs in the transformation of the mercurial salt into the bichloride.

The question whether necrosis takes place in every instance would seem to be settled in the negative by the observation of Du Castel. In a post mortem of a patient who died one month after an injection he found neither necrosis nor any trace of the mercury, showing that complete absorption had taken place.

Incidentally it may be said that pain and local inflammatory phenomena are much less pronounced from the injection of the yellow oxide. Neither Balzer nor Du Castel have ever had an abscess develop from its use. This corresponds with the experience of Schadek, Watraszewki and others, although a greater efficacy is imputed to the calomel. Complications of a general nature, such as ptyalism and diarrhœa are very infrequent from calomel injections. They may be caused by repeating the injections after too short an interval. Constitutional peculiarity or idiosyncrasy, as a presupposing cause, should not be overlooked. I observed two cases of stomatitis, one extremely severe, after a second injection—the other was provoked by a single injection. The more pronounced symptoms of hydrargyrism have never been developed by calomel injections.

From his somewhat extended experience, Balzer regards the curative effects of calomel and the yellow oxide injections as something marvellous. He does not

hesitate to declare that it constitutes the best method known at the present time for the treatment of syphilis. Du Castel, while testifying to its remarkable efficacy, is more reserved in his expressions as to its superior value. He regards it as essentially tentative as yet. Besnier has practically abandoned the method as a means of cure. According to him its use should be restricted to cases in which digestive intolerance is marked, or where the determinations of syphilis show themselves rebellious to ordinary procedures.

As regards the relative disadvantages of the two classes of preparations, so far as immediate effects are concerned, the pain caused by the soluble salts is more intense, while the secondary reactionary phenomena are much more severe, and of longer duration from the insoluble salts.

Salivation is more common after the injection of the soluble salts; but its frequency has been much diminished by greater care in the dosage, and the judicious use of chlorate of potash and other corrigents.

As regards their relative efficacy it would appear that the immediate curative action of the soluble salts is much more pronounced, while the effect of the insoluble salts is more continuous and lasting. All experimenters testify to the remarkable rapidity and energy of the action of mercury when introduced hypodermically.

Independent of clinical experience, the relative value of the soluble and insoluble salts would depend upon the theoretical consideration whether rapidity or slowness of elimination should be the proper measure of the degree of efficacy. In other words, whether the therapeutic specificity of mercury may be best developed by a momentary but energetic action, or by a continuous and prolonged effect. Views differ as to whether an accumulation of mercury in the system acts as a hindrance or help in the cure.

Taking as a point of departure the generally accepted view that the best results are attained in syphilis by keeping the system under specific influence during a long period, medication with the insoluble salts would seem to better fulfil this indication. In fact if mercury acts by sterilization of the tissues, thus preventing the germination of the syphilitic virus, its continued presence in the system would seem to be a necessary condition. The proposal to cure syphilis by the introduction of a supply of the antidote, which, through a process of slow absorption is appropriated by the system as the necessities of neutralization of the virus may demand, may be very ingenious and seductive, but the theory does not rest upon an adequate basis of clinical facts.

Statistics there are in abundance to show that its immediate impress upon the symptoms is most satisfactory. It suppresses manifestations, and hastens their involution. But statistics, we all know, are very elastic and susceptible of a misleading interpretation. The statistics which have been brought forward in support of the much greater permanence of action of mercury hypodermically introduced are valueless on account of insufficient observation.

The experience of Balzer, that patients who have been treated by calomel injections do not return for a repetition of the treatment, while patients who have been treated by ordinary methods return on account of relapses, may be interpreted in two ways—instead of demonstrating the non-necessity of farther treatment, their failure to return may be due to dissatisfaction with the method of treatment. Patients must be kept under surveillance during a number of years, and take no other treatment before the results can serve as a basis for the appreciation of the value of this method.

The claim that 25 centigrammes of the bichloride introduced in quantities of 8 to 10 milligrammes a day for 30 days, or that 40 centigrammes of calomel inserted in 10 centigramme doses at a week's interval, *cures* syphilis, can only be received with incredulity, or the term *cure* must be used in a very loose sense. If we imply by the cure of syphilis what is meant by the cure of psoriasis, viz., a disappearance of the eruption, the characterization may be proper enough; but if it means the definite and absolute cure of the diathesis, the claim is absurd.

Such a result is opposed to our knowledge of the natural history of syphilis, and the limitations of the curative power of mercury as developed by long observation and experience. In the course of the ordinary treatment of the active stage, successive crops of accidents may continue to recur even when the patient is under the full influence of mercury. After the most careful, intelligent and prolonged treatment the conscientious physician cannot give his patient a clean bill of health, or guarantee him absolute exemption from further manifestations of the disease.

In the ordinary conception of the necessities of mercurial treatment, no matter how small the dose, whether the treatment be interrupted or continuous during a period of two to four years, as is generally recommended, a simple mathematical computation will show that a considerable quantity of the drug must of necessity be received—a quantity besides which 6⅔ grains of calomel must appear infinitesimal, even admitting that it is all absorbed. The hypothesis, then, that the introduction of such a relatively small quantity of mercury undergoes some mysterious multiplication of power, which not only suppresses the accidents of syphilis, but makes a permanent impression upon the diathesis, is too severe a tax upon our credulity. It is what Besnier has termed "the romance of mercurial treatment."

One feature of this method, which entitles it to favorable consideration, should not be lost sight of. Its comparative freedom from gastro-intestinal complications, allows us to utilize the gastric functions solely for the reception and assimilation of tonics and reconstituent remedies, and thus enables us to counteract the anemiating and debilitating influence of the diathesis. In the rational treatment of syphilis this class of remedies is scarcely subordinate in importance and value to specific treatment itself.

In endeavoring to appreciate the therapeutic worth of the modern method of treating syphilis, we are confronted by a mass of confusing clinical statistics, as well as a crowd of contradictory statements upon the part of the experimenters, some bearing testimony to its superior efficacy, others depreciating its value and condemning it as obnoxious and impracticable.

A careful weighing of this clinical testimony, balanced by my own observation and experience, justifies the following conclusions:

The hypodermic use of mercury, in simplicity, convenience, scientific accuracy, rapidity of action and the development of a maximum effect from a minimum quantity, constitutes a decided improvement over the ordinary modes of introducing this drug into the system.

The hypodermic method is not so liable to cause salivation, gastro-intestinal disorders and other toxic symptoms of hydrargyrism.

There is a remarkable unanimity of opinion as to its efficacy in suppressing the active manifestations of the secondary stage, and hastening their involution.

The claim that the hypodermic use of mercury increases its potentiality and widens the range of its curative action, enabling it not only to subdue refractory secondary lesions which resist ordinary treatment, but also the tertiary lesions of syphilis, may be considered as yet *sub judice*.

The claim that it endows mercury with a greater permanence of action, preventing relapses and preserving the patient from manifestations of the diathesis for a long period, is not proven.

The more pretentious claim that the hypodermic injection of twenty-five centigrammes of the bichloride, or forty centigrammes of calomel, *cures* syphilis, must be rejected as extravagant and absurd.

The irritant action of mercury introduced subcutaneously, manifest in the production of pain and local accidents, renders its general employment in the systematic treatment of syphilis impracticable.

Until these objectionable features be modified or overcome, the proper position of hypodermic medication in the therapeutics of syphilis is in the category of adjuvants.

Its employment is indicated where the necessities of the case demand a rapid and intense mercurialization. In certain emergencies, when, for example, the integrity of an important organ is threatened, its prompt and energetic action renders it superior to other modes of mercurialization.

In exceptional cases, marital syphilis, for example, where the exigencies of the situation demand secrecy in treatment with the speediest possible suppression of the symptoms, this method is to be recommended.

In cases where gastro-intestinal irritation is so marked as to forbid the introduction of mercury to the stomach, it constitutes a most efficient reserve treatment.

In tertiary syphilis, where the iodine idiosyncrasy is so marked as to preclude the use of iodide of potassium, the hypodermic use of mercury should be substituted.

My own impression is, that while the hypodermic method will never supplant the classic modes of employing mercury, yet it constitutes a decided acquisition to our therapeutical resources against syphilis, too valuable to be ignored or practically disregarded, as has been the case in this country.

66 West Fortieth Street.

SOME POINTS IN THE DIAGNOSIS OF CHRONIC PYELITIS.[1]

By HENRY C. COE, M.D.,
of new york.

Sir Henry Thompson, in discussing this subject from a surgical standpoint a few years since, said: "I have long sought for some sign that should indicate the presence of extensive pyelitis and dilatation, but in vain." Although medical writers do not take quite such a despairing view of the matter, they display a singular unanimity with regard to the difficulty of recognizing chronic inflammation of the renal pelvis, especially when associated with catarrh of the bladder. Only those who possess absolute faith in their ability to positively localize lesions in the urinary tract by examinations of the urine, speak confidently of their power to recognize the existence of secondary pyelitis by the microscope. By "secondary pyelitis," to quote from Ultzmann,[2] "we understand either those forms which have arisen by extension from another part of the urinary canal somewhere below the pelvis, or else such forms as occur from disease about the kidneys, or near the pelvis or bladder." By limiting ourselves to the variety thus defined, we exclude acute inflammation of the pelvis, as well as that due to calculi, tuberculosis, morbid growths, and acute infection; in short, we consider just that form which is most obscure in its inception. This affection possesses more of a surgical interest than it did formerly, since nephrotomy has become quite a common operation, and it is important to ascertain whether we possess any certain means of diagnosticating "pyelitis without a tumor."[3]

I may state at the outset that I shall dwell particularly upon the character of the urine, not only because the positive subjective symptoms are few and indefinite, but by reason of the fact that my personal observations have been confined rather to the former line of investigation.

Certain points in the history are of importance, especially the fact that there has long existed a chronic cystitis. It is impossible to assign any definite period within which we can affirm that the inflammation extended from the bladder to the ureter and pelvis, since the process is essentially gradual and progressive; in other words, although both processes spread by direct continuity, it would be entirely improper to compare the lighting up of a pyelitis with the extension of a catarrh of the bronchi to the bronchioles and air-cells, since in the latter cases the symptoms undergo a sudden and alarming change. The extension of inflammation in the urinary tract is not marked by any such striking phenomena, at least at the beginning. Pain, localized over the region of the kidney, is a later symptom, and is most common in primary calculous pyelitis, when there is usually a history of nephritic colic. "Pain or tenderness, on pressure in the small of the back," says Ultzmann,[1] "is very often mistaken for pain in the kidney." This pain is frequently due to uterine affections, disease of the prostate, etc. As a rule, the vesical trouble entirely absorbs the patient's attention. To cite an illustration: A young woman was under treatment in the Woman's Hospital for three years for intractable cystitis. Cystotomy was performed, and the bladder was washed out systematically through the artificial opening. She was under my daily observation for a year and a half, during which time I examined the urine frequently, with results to be mentioned subsequently. The vesical trouble did not improve, and each time, when the bladder was irrigated, the patient was in great agony; the condition of the organ was such that closure of the fistula was out of the question. At no time, when she was under my care, did I note any symptoms, either subjective or objective, that suggested a renal complication. There was no pain in the loins, and the usual evidences of pus-formation were wanting. The patient's general condition was always bad, but it was to be ascribed to years of suffering rather than to septic infection. She was always able to walk about, and to assist the nurse. A few months later she began to have pain over the left kidney, and when examined under ether an enlargement could be imperfectly made out in that region. Subsequently nephrotomy was performed at the New York Hospital with a fatal result, the diagnosis being confirmed by the removal of a moderately enlarged kidney, the pelvis of which was filled with pus, while the parenchyma was riddled with abscesses. The opposite organ was healthy. I could mention several other cases of chronic cystitis in females in which well-marked pyelitis and pyelo-nephritis were found at the autopsy, although their presence had not been recognized during life, owing to the greater prominence of the vesical symptoms. The cause of death was septicæmia, a condition which was clearly evident from the final symptoms.[2] But the absence of positive evidences of secondary inflammation of the pelvis is by no means confined to females, in whom pelvic complications may readily divert our attention from the renal affection; stricture and hypertrophy of the prostate are frequently followed by inflammation high up in the urinary tract, but "pyelitis," under these circumstances, is milder in character, does not occasion any severe symptoms, and goes, for the most part, unnoticed by patient and surgeon.[3] Among the physical signs I know of none (in the absence of an actual tumor) which is at all definite, except pain and tenderness over the affected kidney, and this is more often absent than present.

Such being the unsatisfactory result of our efforts to discover evidences of pyelitis from the history and examination of the patient, we are forced to the conclusion that whatever positive information there may be must be furnished by the urinary analysis. Yet, in the form of pyelitis which we are considering the analysis is often negative, because the urine "bears the stronger impress of the vesical, prostatic, or urethral disorder."[4] In my

experience this "stronger impress" is frequently noted during the examination of sediments, and is a most perplexing factor, obscuring the true condition in cases of well-marked renal disease. Nor is this true only of the acute form of the affection under discussion. In an exquisite case of acute pyelitis following a gun-shot wound of the right kidney, in which, by repeated examinations, I was able to follow the course of the healing process quite easily, although the first few specimens showed under the microscope the typical appearances described in the text-books, a vesical catarrh speedily developed which obscured the original condition, so that a chance observer would doubtless have failed to detect in the urine evidences of an acute process in the renal pelvis. After the inflammation of the bladder had subsided, it again became possible to recognize the pyelitis. It is usually stated that in chronic pyelitis the amount of urine passed in twenty-four hours is increased, while the specific gravity is low. This polyuria is explained in part by the presence of cardiac hypertrophy, and in part by the disturbance of the normal osmosis when the disease has extended to the medullary portion of the gland. Doubtless we often imagine that the amount of urine is greater because the patient is obliged to urinate frequently in consequence of vesical irritation. Since the proportion of the normal constituents is commonly unaltered, the presence of an excess of uric acid or phosphates (especially of a considerable crystalline sediment) might properly awaken the suspicion that there was a renal calculus. As regards the general appearance of a given specimen, I should be inclined to regard the presence of a thick deposit of pus, without an excess of mucus, as quite important, especially where there was only moderate catarrh of the bladder, since if an equal amount of pus came from the bladder *alone*, there would be a large quantity of thick, ropy mucus, which would adhere to the bottom of the vessel. I have found this negative point of considerable value in obscure cases, especially when the urine was neutral or only slightly alkaline, since a strong alkaline reaction would be significant rather of chronic cystitis; the presence of the latter condition, of course, usually renders both of these tests nugatory. Ultzmann[1] insists that "albumen appears constantly in greater amount than corresponds to the contained purulent sediment." It rarely exceeds one-fourth of one per cent. It is difficult, if not impossible, to determine this point when pus is present in excess. Diminution in the relative amount of urea is sometimes noted in advanced cases, and is to be regarded as of serious import. Pascallucci[2] calls attention to the fact that in pyelitis nitrate of urea crystallizes in feathery forms not in rhomboidal shape as in cystitis. The sediment is essentially purulent, and the amount and manner of appearance of this pus are important. It sometimes diminishes in amount for a short time, and then there comes a sort of gush as if an abscess had ruptured, although there has been no evidence of such a condition. In case of doubt it is well to adopt Thompson's plan of washing out the bladder thoroughly and then introducing a soft catheter, which is allowed to remain *in situ* until a small amount of urine has flowed through it. If this specimen contains a large amount of pus, and a second washing of the bladder brings away an insignificant amount, we may infer that the pus came from higher up in the tract.[3] This separation of the pelvic and vesical urine is readily accomplished in the case of a patient now under observation, from the fact that a fine catheter can be passed directly into the pelvis of the kidney through a uretero-vaginal fistula. This is an unusual opportunity to study the different appearances of the excretion in pyelitis, cystitis, and also when the two specimens are mingled. I must acknowledge that the differences have not been as striking as I could wish for the sake of deducing rules for exact diagnosis. Thus one specimen of urine withdrawn directly from the pelvis was similar in all respects to one from the bladder, except that vesical epithelium was absent. The sudden discharge of quantities of pus was noted in the case of artificial vesico-vaginal fistula to which I alluded, but in this instance there was such an aggravated cystitis that it was seldom possible to obtain a specimen which did not deposit a thick, ropy sediment. As regards the presence of blood, I need only add that when it is really derived from the pelvis, as may be determined by Thompson's test, it should awaken the suspicion that the pyelitis is not simple, but is associated with a morbid growth or calculus; the latter may, of course, be *secondary* to the pyelitis. When, as in a specimen which I examined, there is present a considerable quantity of fresh unchanged blood, we must infer that it is derived from some point lower down in the ureter, possibly in consequence of catheterization of that duct.

As regards the microscopical appearances, I must confess that I have found many of the descriptions at fault. There are some writers who seem to base the diagnosis of pyelitis entirely upon the presence in a given specimen of a few caudate-cells such as are known to line the pelvis and calyces; others even profess to be able to recognize the extent of the inflammatory process by noting whether this transitional epithelium came from the superficial or deep layer. Now, applying the same principle here as we do in inflammation of any mucous membrane, it is evident that the stage of desquamation is that of acute catarrh, while after the process has become general and necrotic, the epithelial lining is destroyed. "Epithelial cells," says Ultzmann, "are very sparingly present in chronic pyelitis; and if the suppuration is very severe, they may be entirely wanting, since they apparently by endogenous cell-formation break up into pus-corpuscles." I have found large flakes of pelvic epithelium in a case of secondary pyelitis, where the next half-dozen specimens contained only here and there a cell. How unscientific it is to locate an inflammatory process in the urinary tract by finding three or four characteristic epithelial elements in a single slide! "One swallow does not make spring," and one cell does not furnish us with a perfect mental picture of the pathological process which is taking place in the region from which it came, even if such a process is present. Strange to say, we admit that constant exfoliation of cells is taking place in all the other mucous passages, yet in the case of the urinary tract the appearance of a few leucocytes and pelvic cells in the urine is regarded as proof positive of pyelitis. We may safely assume, then, that, while the presence of large numbers of pelvic epithelia furnish us an important aid in the diagnosis, their absence is by no means an argument against the existence of chronic pyelitis. The pus-corpuscles themselves are worthy of careful study. They are more apt to be arranged in sheets or masses, than is the case when they are derived from the bladder. Ultzmann has described and figured "purulent plugs of the ductus papillares," which he regards as peculiar to this condition; these sometimes contain cells from the tubules. Renal epithelium is commonly found, and by its amount we can estimate roughly the degree of disturbance in the medulla. In decomposed urine from a diseased bladder the finer objects may be obscured by an excess of amorphous urates. In like manner the presence of crystalline phosphates, bacteria, etc., will possess no special significance. But if such a sediment was deposited from a specimen of urine drawn directly from the pelvis (as in the case of ureteric fistula), it would point to a decomposition occurring within the kidney, when a secondary calculus might readily be formed. But since our opportunities for catheterizing the renal pelvis are rare, we are obliged to base our diagnosis upon the appearance of the urine as it is withdrawn from the bladder; and if the latter is the seat of chronic inflammation, it can be readily inferred that even an expert in urinaly-

sis would be unable to give a positive opinion from the examination of a single specimen.

In the presence of such a complication, and knowing nothing about the history of the patient, I should be inclined to lay most stress on the relatively large amount of pus and albumen and the small amount of mucus. If pelvic and renal epithelium is present in considerable amount, so much the better.

In conclusion, I shall quote from a well-known authority on diseases of the kidney:[1] "The upper urinary passages are likely to be involved when the quantity of pus is very great—two or three ounces, or more, per day; when, with a large discharge of pus, the urine is only feebly ammoniacal; when the loins are painful on pressure, and the febrile movement and the decay of strength seem out of proportion to the vesical or urethral mischief; lastly, when the latter has been in existence for several years."

ANEURISM OF THE INNOMINATE ARTERY, TREATED WITH LIGATURE OF THE RIGHT CAROTID AND SUBCLAVIAN ARTERIES.[2]

By HERMAN MYNTER, M.D.,

SURGEON BUFFALO GENERAL HOSPITAL.

The following case, although not of very rare occurrence, is of sufficient importance to deserve mentioning. The patient is a married woman, fifty-four years of age, who consulted me in May, 1887, on account of increasing dyspnœa, difficulty of swallowing, palpitations of the heart, and a pulsating tumor of the jugulum.

She belongs to a healthy family, has had seven children, of which four died in infancy. She has never had syphilis, but years ago had several attacks of inflammatory rheumatism. She lost a daughter five years ago, and worried for a long time over her loss; was sleepless, and commenced since then to complain of palpitations of the heart. Her periods ceased, and for three years she suffered from continual diarrhœa, became weak and emaciated, losing thirty pounds in weight. The diarrhœa stopped a year and a half ago, and she noticed then rheumatic pains, and a heating on the right side of the neck, just under the sternal end of the clavicle. At the same time the palpitations of the heart grew more severe, and she complained of occasional faintness and dizziness, and increasing dyspnœa. It became, little by little, more and more difficult for her to swallow her food; and she noticed a small, pulsating, painless tumor in the jugulum, which slowly grew larger, exerting pressure on the adjacent organs, and causing pain of a gnawing and pressing character.

For six months before the consultation she was unable to lie flat on her back, from pressure of the tumor on the trachea, and at times she found it hard to breathe and swallow. By the least exertion the tumor beats with increased violence. Her appetite was fairly good. At the examination she looked congested and bluish in the face. On the chest were seen a number of large veins, pulsating synchronous with the pulse.

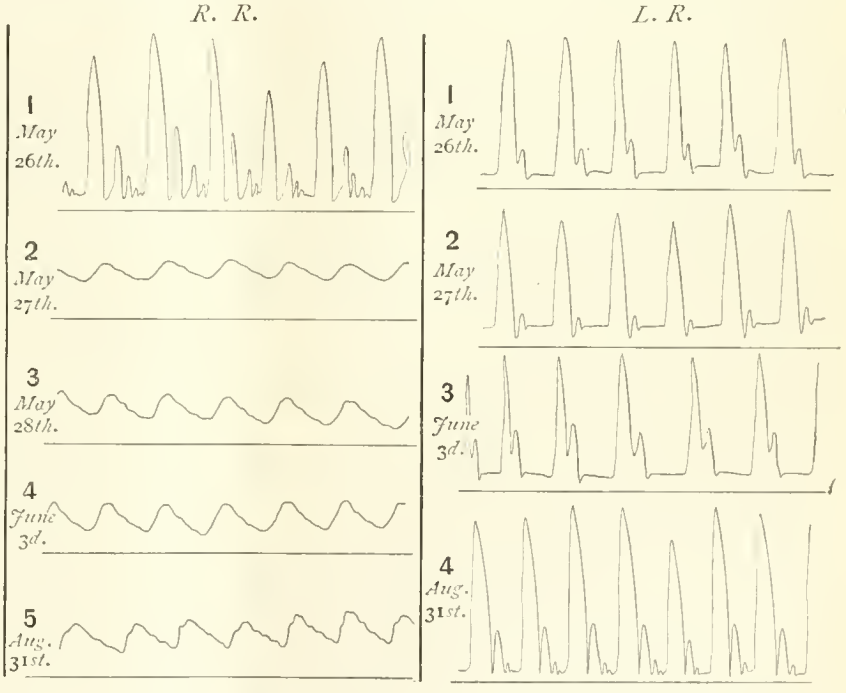
In the interclavicular space, extending upward behind the sterno-mastoid muscle, a pulsating tumor was seen, as large as a large walnut, which expanded synchronous with the pulse. It was rather soft, and by pressure could be made smaller. It was not painful upon pressure. The heart was enlarged, the impulse of the apex being outside the papillary line. A systolic murmur was heard over the whole heart, increasing upward. To the right of the sternum an aortic obstructive and regurgitant murmur was heard. A diastolic anæurismal murmur was heard over the tumor, extending upward into the carotid and outward into the subclavian arteries. A vibratory thrill could be felt synchronous with the heart-impulse. Two inches above the tumor the carotid artery pulsated, seemingly normally, and the artery appeared of normal size.

The laryngeal examination showed the larynx to be normal, with no paresis at the nasal cords.

Pulse, 90; soft, and easily compressible. She was ordered rest in bed, restricted diet, large doses of iodide potash, and a dessert-spoonful of infusion of digitalis three times a day. She did not improve during the next fourteen days; the dyspnœa increased till it was almost unbearable; the aneurism grew slowly larger; she was sleepless and rapidly losing ground. I, therefore, advised immediate operation, and she entered the General Hospital for that purpose, on May 25, 1887.

May 26th.—Operation under ether-narcosis, a large number of physicians being present. Under strict antiseptic precautions, the common carotid, and the subclavian arteries were ligated with heavy catgut, the carotid in the middle, the subclavian in its third division, outside the scalenus anticus muscle.

The wounds were sutured with catgut, having first been irrigated with corrosive sublimate (1—1000), and a complete sublimate bandage applied, under which union by first intention took place.



May 27th.—A faint pulse returned in the radial artery this evening, and a sphygmographic trace was taken, which shows a mane, but without arterial tension. The patient rallied well, right arm and right side of face, colder than on left side, and feels numb.

May 30th.—Patient comfortable, temperature normal, pulse on left side 88°, strong and full.

June 2d.—The wounds are dressed for the first time, and are found closed by first intention, without a trace of matter. The aneurism is smaller, harder, and the pulsation has considerably decreased. There is seen and felt considerable pulsation of the arteries from the thyroid axis, especially the inferior thyroid, and the transversalis colli.

[1] Roberts—op. cit., p. 468.

[2] Read before the Buffalo Medical and Surgical Association.

No pulsation can be felt on the distal side of the ligatures; the right radial pulse scarcely perceptible to the finger, but the sphygmograph shows a mane. She can lie down flat on her back without trouble, has less dyspnœa, and swallows with greater ease.

Surface thermometer shows 1-2 degrees less on the right side.

June 6th.—Patient allowed to sit up pulse in right radial has more volume.

June 15th.—Patient discharged.

August 31st.—Patient has since felt pretty well, and is able to do some light house-work, can walk a considerable distance (half a mile,) without difficulty. No trace of the aneurism is found, but the innominate artery can be felt pulsating, and seems a little larger and firmer than normal. The pulsation of the arteries from the thyroid axis is seen only occasionally, after excitement. The pulse of the right radial is felt but weaker than on the left side; no pulse yet in the right temporal artery.

She eats with appetite, and swallows without any trouble, has no dyspnœa worth mentioning, sleeps well, and can lie on her back, and may be considered cured, as far as the aneurism is concerned.

This operation, if not very rare, is of infrequent occurrence, and is justly considered a formidable undertaking. Dr. Rosenstern, of San Francisco, has lately published in the *Archiv für Klinische Chirurgie*, Band 34, 1887, a monograph about aneurism of the arch of the aorta and of the innominate artery, in which he has gathered together ninty-nine cases, all operated and divided into several sections.

In simultaneous ligatures of the carotid and subclavian arteries, he has found thirty-eight cases, of which sixteen were cured, five improved, six not improved, and eleven died. With my case and one cured by Professor Ashhurst, of Philadelphia (reported in the *Medical and Surgical Reporter*, July 16, 1887), we have eighteen cures in forty cases, or 45 per cent. of recoveries, a rather favorable showing for so serious a lesion.

In ten cases the carotid artery was first ligated, and sometime after (from two days to two years), the subclavian, and of these one recovered, six improved, two not improved, and one died, the recoveries being 10 per cent.

The right carotid was ligated alone in thirty-one cases, of which five recovered, two improved, two not improved, and nineteen died, being 16 per cent. of recoveries.

The right subclavian was ligated alone in five cases, of which two recovered, one improved, one unimproved, and one died, being 40 per cent. recoveries.

Lastly, the left carotid artery was ligated alone in ten cases, of which two recovered, four improved, one unimproved, and three died, being 30 per cent. recoveries.

Of course, the number of cases in three of these divisions is too small to base reliable statistics upon. It must be remembered, too, that a number of these cases were operated upon before the antiseptic period, and before catgut was used as material for the ligature; and it is more than probable that the percentage of recoveries will increase with our improved modern methods. Anyway, the simultaneous double distal ligature shows by far the highest percentage of recoveries, and is the most successful.

Of other methods, several deserve mentioning. Tufnell's method is the old Valsalva method, less the venesections, the patients being kept on their backs for months on a very restricted diet.

Balfour does the same, but adds large doses of iodide potash. Both mention cures, but authors differ in their opinions in regard to these methods, although recommending them, if there are no absolute indications for immediate operation.

Moore was the first to introduce antiseptic coils of wire or catgut into the sac to favor coagulation, and the operation has been repeated a few times both here and abroad; the method produces, besides coagulation, an inflammation of the sac, and is not without danger, both from embolus, suppuration and rupture of the sac. In thoracic and abdominal aneurisms, which can be treated in no other way, this method may now and then be found of advantage. The same may be said of electro-puncture, which has been tried in a number of cases, mostly on the descending aorta, with some recoveries. The operation had to be repeated often, and several patients have died shortly after the performance. The danger of embolus would, of course, be much greater if performed upon an aneurism of the innominate artery. Rosenstirn thinks electro-puncture might be of use following the ligation of the carotid and subclavian.

In regard to diagnosis, Rosenstirn thinks it almost impossible to distinguish between aneurism of the innominate and the arch of the aorta, and that both are present in the majority of cases.

The paresis of the laryngeal muscles, if present, is of diagnostic value, and possibly the sphygmographic traces. If the left recurrent nerve is the affected one, it shows that the transverse or descending aorta is affected. If the ascending aorta is primarily affected, the right recurrent nerve alone will suffer, but generally rather late in the course of the disease, after the tumor has appeared at the root of the neck.

In aneurism of the arch of the aorta pressure-symptoms come early in the disease, and are more severe than in the innominate aneurisms; absorption and ulceration of the costal cartilages are not infrequent. The innominate aneurism generally appears above the sternum, either between the two heads of the sterno-cleido-mastoid muscle, or in the interclavicular notch. There is always some difference in the pulse, recognizable at least in the sphygmographic trace of the two arms, while in aorta aneurism the pulse is alike, unless the innominate is compressed. A new symptom of thoracic aneurism has lately been pointed out by Dr. Drummond, of Newcastle, and reported in the *Medical Press*. If a patient suffering from thoracic aneurism is made to draw a long breath and then close the mouth and expire slowly through the nose, short puffing expiratory sounds are heard on the trachea synchronous with the systole of the heart, and, according to Dr. Drummond, due to the sudden systolic expansion of the sac expelling air from the chest.

Lastly, I wish to call the attention to the accompanying sphygmographic traces, taken by Dr. Henry Hopkins, who saw the patient with me in consultation. From them we get some important information both in regard to diagnosis and prognosis, although they are blended on account of the existing severe valvular heart-trouble. The first traces of both radial arteries, taken the day before the operation, show great elasticity of the arterial walls by the steep and high upstroke, excluding arteriosclerosis with rigid walls, and probably excluding a dissecting aneurism, which generally depends upon arteriosclerosis.

The steep and abrupt down-stroke, going farther down than usual, is the result of the insufficiency of the aortic-valves, by which the blood is allowed to churn backward and forward under the influence of the elastic recoil, and consequently shows greatly decreased arterial tension. The dicrotic wave is much larger in the right radial than in the left radial artery.

The dicrotic wave is generally described as a wave of oscillation, reinforced by a wave of expansion from closure of the aortic valves, and is, according to Foster's "Physiology," favored, 1, by sudden strong ventricular systole; 2, by low tension; 3, by elasticity, and consequently extensibility of the arterial walls, the three conditions we have in this case.

The difference in the dicrotic wave, it being larger on the right side, may possibly be pathognostic of aneurism of the innominate artery, and may be the result of the contraction of the aneurism during diastole, by which an

increased amount of blood is circulating through the right subclavian and its branches, giving increased arterial tension, and greater arterial expansion on this side.

The sphygmographic trace shows no perceptible difference on the left side after the ligature, and especially no higher arterial tension, which we might have expected, considering that the two large arteries were cut off from the circulation, while the amount of blood was the same; of course the valvular heart-trouble may be the cause of it. The pulse jumped immediately after the operation from 88 to 102, increased during the next day to 114. It commenced then gradually to decrease again until the fifth day, when it again was, and afterward continued to be, 88.

The increased frequency of the heart-beat, of course, compensated the cutting off of the two important arteries from the circulation. The traces numbers two, three, and four of the right radial artery, taken after the ligation, are simple undulations without any character, yet showing gradually increased arterial tension, especially pronounced in number five, and characterized by the sustained and gradually descending downstroke. That the arterial tension has gradually increased on the right side I consider the result of the ligation of the subclavia, as the valvular heart-lesion is unable to produce its influence on the radial artery through the circuitous route of anastomases, made necessary by the subclavian ligature.

I will add that the conclusions I have drawn in this case from the sphygmographic traces, are entirely at variance with the rules laid down in text-books. Barmell, for instance, in the "Encyclopædia of Surgery," vol. iii., p. 525, asserts that the sphygmographic trace "shows a sloping and low upstroke and an absence of tidal and dicrotic waves, so that, for instance, in an aneurism of the innominate, or of either subclavian, the line may represent a mere succession of even and shallow undulations." The whole subject of sphygmography is yet in its infancy as applied to aneurisms, and contributions on this subject, therefore, may deserve some attention.

Acute Hepatic Cirrhosis.—The varieties of hepatic cirrhosis are very numerous, and the tendency is rather to increase their number, while the desire must surely exist to put this seeming chaos into order. Much light has yet to be thrown on the acute forms of cirrhosis, with which we seem to be becoming more and more familiar. M. Debove has published an account of an interesting case (*The Lancet*). The whole duration of the clinical history was not more than five months, and for the first three of these the woman, aged thirty-four, merely complained of some general symptoms not specially referable to the liver, the first symptom of affection of which organ was marked jaundice. On admission to the hospital it was found that the liver extended five fingers' breadth below the margin of the thorax. Fever, jaundice, hemorrhages, enlargement of the spleen, diarrhœa, and but slight ascites, were the principal symptoms. Three weeks before death the liver progressively diminished in size, till at the necropsy it was found to be level with the edge of the ribs. The cirrhosis had chiefly affected the periphery of each hepatic lobule, and was in this sense allied to the mono-lobular form of Charcot, for the amount of connective tissue increase was about sufficient to replace that of true liver tissue, so that the volume of the organ was not far from normal. Further examination showed, however, that a peri-cellular sclerosis had also taken place, and that the connective tissues around the portal system as well as around the hepatic veins were increased; the surface and section of the organ were granular. The remaining true liver-cells were either fattily degenerated, recalling the fatty cirrhotic type, or else granular and atrophied. Debove believes that neither alcohol nor syphilis was operative in the causation of the disease, which he was unable to explain.

A QUESTION OF PRIORITY CONCERNING A NEW THEORY OF THE ETIOLOGY OF CONGENITAL CLUB-FOOT.

By HENRY W. BERG, M.D.,

NEW YORK.

To *The Lancet* of June 29, 1887, R. W. Parker, of London, contributed a paper, which was published under the head of "Original Articles," entitled, "On Congenital Club-foot." Anxious, however, that the readers of *The Lancet* might not be misled by the title, the author states in the opening paragraph that he will make the observations a sort of "criticism on a paper published *two years ago* (the italics are mine) by Dr. H. W. Berg, of the New York Orthopædic Hospital, in 'Seguin's Archives of Medicine' (vol. viii., No. 3, pp. 226–248), now defunct, in which this author raises most of the points in dispute."

The pleasure I should have taken in perusing an "original article" devoted to a "criticism" of my paper, was marred by a very important misstatement in this introductory paragraph above quoted, namely, that my article appeared only "two years ago." The blunder is the more unpardonable in that the reference (vol. viii., No. 3, etc.) is absolutely correct. A little more of the scholarly exactitude here displayed would have shown that the date of the issue corresponding to this reference is *December*, 1882, more than *five and a half* years previous to the publication of Dr. Parker's "original article" in *The Lancet*. Mr. Parker subjects himself to the risk of suspicion that the error was a wilful one, when it is known that in conjunction with Mr. Shattuck he published and widely circulated an original article on the "Pathology and Etiology of Congenital Club-foot," the reprint of which bears the date 1884, almost two years subsequent to the monograph entitled the "Etiology of Congenital Talipes Equino-varus," which has excited the attention of Dr. Parker at this late period.

In the *American* (not at that time the *International*) *Journal of Medical Sciences* of July, 1886, this paper of Drs. Parker and Shattuck received what Mr. Parker calls a "friendly notice." This "notice" consisted in a polite intimation that many of the views advanced in the paper had been promulgated by myself some two years earlier, and expressed surprise that *no reference to my paper* was made by Drs. Parker and Shattuck. The critic further continues: "The American contributor has carried his observations, repeated with the most striking similarity by Drs. Parker and Shattuck, a step in advance of the authors, and followed them to their legitimate logical conclusions, which for some reason Drs. Parker and Shattuck have avoided."

It is this "friendly notice" which has called forth the original article, or rather criticism, in *The Lancet*, with which Dr. Parker has honored me.

My paper, as I have already stated, had appeared in Professor Seguin's *Archives of Medicine*, a bi-monthly of excellent standing, to the discontinuance of which Dr. Parker so elegantly refers, and although I had not scattered reprints abroad, yet reference to recent literature should have revealed to Drs. Parker and Shattuck the existence of a monograph, the title of which showed its purpose to be identical with that of the paper they were projecting. Had the two papers, however, been simply similar in title, neither the American critic whom I have quoted, nor my medical friends, nor myself, could or would have complained at the apparent neglect to refer to my paper. But the points of similarity in the two papers were numerous, and to me almost startling. Of course, I refer here only to that part of Drs. Parker and Shattuck's paper, and it is by far the chief portion of their work, which refers to the etiology of congenital club-foot, my own paper being concerned only with this portion of the subject.

In both papers the method of study adopted to arrive at the etiology of club-foot was the same. This was the

more remarkable in that no other observer before myself had worked by this method. I had applied embryological data obtained from the recent researches of eminent embryologists to the study of fœtal specimens in the museums of New York and Bellevue Hospitals, to which I referred by number as catalogued, and had arrived at results which, to the best of my belief, I thought original. Two years later Drs. Parker and Shattuck apply the same embryological data, without reference to the authorities from whom they were obtained, to the study of fœtal specimens in the museums of Guy's, St. Mary's, St. Bartholomew's, and St. Thomas' Hospitals, to which they refer as catalogued, and arrive at similar results. In my paper I premise the results obtained by myself by a *resumé* of the generally accepted theories of the etiology of talipes. Drs. Parker and Shattuck very properly, as I think, do the same. Indeed, occasionally the similarity of the two papers is sufficiently close to justify me in the following parallel quotations :

DR. BERG'S PAPER, PUBLISHED DECEMBER, 1882.	DRS. PARKER AND SHATTUCK'S PAPER, PUBLISHED MAY, 1884.
Page 227.	Page 10.
"Orthopædic writers may be divided into two classes as regards their views concerning the causation of congenital talipes equino-varus. 1. Those who consider the deformity the result of a mechanical force acting upon the fœtus in utero. 2. Those who consider it the result of disease (intra-uterine), whether of the osseous, muscular, or nervous systems."	"Causes which are usually invoked to explain the production of talipes. These causes may be classed as, 1. Nerve causes, leading either to paralysis or spasm of certain muscles. 2. Bone causes. 3. Mechanical causes (interlocking of parts, pressure due to environment,) etc."
Page 233.	Page 11.
"Finally, to reason that because talipes occurs with the above conditions " (neuroses, anacephalous monsters, hydrocephalus, etc.) "these conditions are necessarily the cause of all cases of congenital talipes, is illogical."	"It is argued that because talipes ensues after certain recognized nerve-lesions, a nerve-lesion must therefore be the cause of those forms of talipes which are congenital," etc.
Page 234.	Page 11.
"First, a mere objective examination of a case of congenital talipes and one of infantile paralysis reveals various points of difference. In the first the leg is fat, well-nourished, and of normal surface temperature, showing no signs of the muscular atrophy and cold surface which are characteristic of the second."	"In cases of infantile paralysis . . . when talipes does supervene there are other unmistakable signs of nerve-lesion, viz., general atrophy of the limb, with lowering of temperature." "If we contrast these atrophic conditions with the well-nourished, warm limb of the majority of cases of congenital talipes," etc.
Page 238.	Page 17.
"It will here, then, be instructive to study the main facts in the process of the development of the lower extremities, dwelling upon those points only which are of importance in the present discussion."	"With a view, therefore, to further elucidate this subject we have turned our attention to a consideration of the positions of the lower limb during its development and growth, considering also some of the morphological questions thus raised."

Then follows, in both the American and London papers, an account of the changes which the extremities, particularly the lower, undergo in the course of their development, my own account being far more complete and extensive. Space will not permit me to quote *in extenso*. I can only feel flattered at the accord between my views and those of Drs. Parker and Shattuck, published two years later. This agreement, however, is not maintained throughout; for in my paper, I am careful to specify that I consider club-foot the result of the prolonged maintenance of the position of the lower extremity proper in the early months of uterine life, into the later months of uterine life; rotation inward of the lower extremity not having occurred, or having occurred too late to overcome the talipes, which was the result of the early uterine position, and which was normal up to a certain period of uterine life. Drs. Parker and Shattuck, however, while accounting for the occurrence of club-foot in exactly the same manner as I do, explain the non-rotation inward, or retarded rotation inward of the lower extremities, on the theory that it has been prevented by some *mechanical* cause, such as the interlocking of the feet of the fœtus, or pressure of the uterine walls when the liquor amnion is deficient in quantity, preventing the further rotation inward of the lower extremities; which, after all, places them in the group of those "who consider the deformity as the result of a mechanical force acting upon the fœtus in utero." In speaking of these, I say: "Apart from the fact that the fœtus in utero is not an inert mass, but a living being which moves about in its surrounding fluid and does not maintain its feet in any fixed position, the theory has this objection—that other parts of the body which, under similar circumstances, should be subjected to a similar position, are not found with equal frequency to have acquired their false position. How long would interlocking of the feet, for instance, be maintained by this active fœtus? I do not find it necessary to conceive the fœtus as subjected to sufficient pressure to prevent use of its joints, in order to account for the non-occurrence of the inward rotation of the lower extremities. On the contrary, the fœtus stretches its joints to the full extent possibly in the early outwardly rotated condition of the limb. But since, in this condition, the foot is for the most part maintained in the position of equino-varus, as a study of my embryological specimens will show, it will, if not rectified by the later inward rotation of the leg, result in a club-foot at birth. To quote again from my paper: "Here I wish to call attention to the fact that no extraordinary amount of intra-uterine pressure is necessary to produce this deformity, its cause being not pressure, but, as we have seen, a retarded rotation inward of the lower extremities.

"This I maintain, in spite of the accidental occurrence of pressure-marks on the feet of a few club-foot children, and notwithstanding the observation, in an equally small number of cases, that the birth of a child with pes-equino-varus was accompanied by a deficiency in the amount of liquor amnii, while such deficiency is more common with normal fœtus.

"*Every* case of congenital equino-varus will show evidence of the condition to which I have ascribed the deformity—namely, non-rotation inward of the lower extremities." In the large majority, and perhaps all, of the children with congenital equino-varus, the knee will be found looking outward and only slightly forward.

A careful consideration of *all of the points* raised in my paper, even at this late date, will, I am convinced, make Mr. Parker an entire, instead of partial, convert to the "retarded rotation theory," if I may call it such, of the production of club-foot. I use the word "convert" advisedly.

We have positive proof that as recently as May, 1880, the importance of the non-occurrence or retardation of the inward rotation of the lower extremities at the proper period of fœtal life, as an etiological factor in the production of talipes, either in whole or in part, had not even dawned upon the mind of Mr. Parker. For in the "Transactions of the Lond. Path. Soc.," vol. xxxi., page 370, May 4, 1880, we find that Dr. Parker presented the pathological specimens of two cases of club-foot, one a case of congenital talipes-varus from an "anacephalous fœtus which died at birth, and a second of congenital talipes calcaneus from an otherwise normal fœtus, which also died at birth. *Apropos* of these two specimens, although presented chiefly as an "interesting contribution to the pathology of congenital talipes," Dr. Parker said a few words concerning his views as to the etiology of talipes. He says: "Various views have been expressed as to the causation of such deformities. I venture to think that these two specimens show how malposition in utero is probably the real predisposing cause of the congenital forms of the disease. Given a faulty position of the limb, the result of a jolt, or a fall, or a blow sustained by the mother, or of some irregular mus-

cular contraction of the uterus, and we have all that is necessary to bring about this deformity." So plain a statement of the old mechanical theory of the causation of club-foot, a theory so old that it has become fixed in the minds of even the laity, induced me to refer to Dr. Parker in my own monograph, as being one of those who believe in this rather antiquated mechanical theory, although I might well have been pardoned for overlooking Dr. Parker's views entirely, since this contribution consisted of only a few paragraphs, and was only of importance as presenting two pathological specimens. Although we thus see that in May, 1880, Dr. Parker's views were entirely different from those of 1884, yet in *The Lancet* criticism, Dr. Parker refers to the few paragraphs of 1880 as his "first paper," and to what is really his only paper, as his "later, more detailed and illustrated monograph."

In the "original article" which Dr. Parker devotes to a criticism of my paper, he says: "We can both afford to say nothing about priority. Moreover, *our* interpretation of club-foot rests not so much on individual work as may well be seen from the rich bibliographical references contained in Dr. Berg's paper, as on the application of that of many workers in the various branches which constitute scientific medicine."

From what has been said as to the dates of publication of our respective papers, there is no doubt that Dr. Parker can well "afford to say nothing about priority," and to the intelligent reader it is hardly necessary that I should say anything about priority; the facts speak for themselves. Nor do I claim to have developed the whole subject of human embryology. I am not too proud to be a disciple of such observers as Professor Humphrey and Albert Kölliker; and if one is able to apply any of the abstract scientific facts which their genius has elucidated, to a practical point in the etiology of disease, I consider that some credit for originality is due. Wherever I have thus taken scientific facts, I have invariably stated the source where they were derived, so that the reader is not misled. Eschricht's work I did not refer to, for the reason that I was entirely ignorant of it until Dr. Parker mentioned it in the criticism to which this article is an answer. If, however, Dr. Parker considered this writer to have advanced many of my views, and therefore many of his, as far back as 1851, I am surprised that Dr. Parker does not mention him or his paper in this monograph. Dr. Parker, although calling my attention to Eschricht's paper, entitled "Ueber die Fœtalkrümmungen, namentlich in Bezug auf die Bedeutung der angeborenen Verdrehungen der Bauchglieder," unfortunately did not give me the reference. My friend, Dr. Gibney, however, with his extensive bibliographical knowledge, came to my aid, and sent it to me. The reference is, *Deutsche Klinik*, Bd. iii., November 1, 1851, p. 467. I found the article in the New York Hospital Library, and upon reading it regretted that I had not seen it soon enough to save some labor. The portion of the article which refers to club-foot is only about half a column in extent, but it is sufficient to show that Eschricht, together with Geoffry St. Hillaire and Wagner, whom I quote in my monograph, was one of those who were aware that the fœtus at a certain period of its existence (third to fourth month, Wagner; sixth to seventh week, Geoffry St. Hillaire) is club-footed.

"In exactly what changes"—I quote from my monograph—"the normal process of development consisted, and how the foot gained its normal position, they did not understand." I believe that this would be true of Eschricht also, unless his original publications, which, being in Danish, I am unable to read, should prove to be more extensive.

In conclusion, I would assure Dr. Parker that I should have replied to his *Lancet* "criticism" sooner, had I not been prevented by the press of general practice

A NEW METHOD OF EXCISION OF THE ANKLE-JOINT WITH REMOVAL OF THE ASTRAGALUS.

By JOHN A. WYETH, M.D.,

PROFESSOR OF SURGERY, NEW YORK POLYCLINIC; SURGEON TO MOUNT SINAI HOSPITAL.

The success of the operation to be described depends upon: 1. The careful removal of all diseased tissues in the field of operation.

2. The cleanliness (asepsis) which is obtained by the careful and judicious employment of sublimate-irrigations and dressings.

3. The accurate adjustment of pressure, together with the employment of position to prevent oozing after the tourniquet has been removed.

Operation.—The leg and foot of the diseased extremity should be carefully washed with soap and warm water, cleanly shaved, and the foot immersed for five minutes in a vessel containing a 1-to 3000 warm sublimate solution. When sinuses exist, they should be cleansed by irrigation with the same solution. The foot should now be elevated to allow the blood to gravitate to the centre, and while in this position the Esmarch bandage applied, commencing at the toes, proceeding as far as the diseased tissues, then skipping over the joint, and continuing to above the knee, where the tourniquet should be adjusted, after which the rubber bandage is removed. The field of operation should be again washed with sublimate solution, and then with ether.

Commence an incision on the internal surface of the tibia, about two inches above the tip of the inner malleolus, and carry it directly down to this point and thence forward from one inch to one inch and a half along the tarsus in the line of the metatarsal bone of the great toe

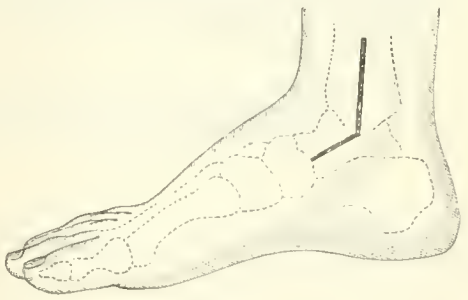


Fig. 1.

(Fig. 1). This incision extends a little anterior to the astragalo-scaphoid articulation. A light L-shaped incision is made upon the fibular side of the joint (Fig. 2). With

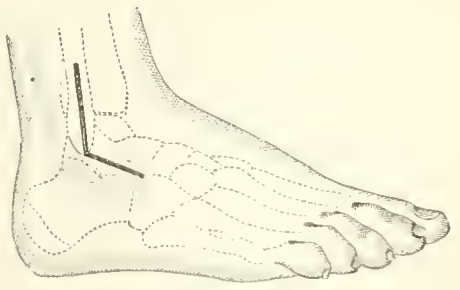

Fig. 2.

the Sayre periosteal elevator, lift from the diseased portions of bone the periosteum (with its attachments to the superjacent soft tissues undisturbed). Expose the outer malleolus and fibula as high as it is deemed necessary to remove this bone, and divide it with the exsector or chisel. As soon as the piece is removed, the joint is thoroughly exposed to view. Now, in the line of the tibial incision, further lift the periosteum of the tibia and tarsal bones, and, by forcibly bending the foot inward, dissect the tibia and inner malleolus outward through the wound on the fibular side. The diseased surfaces of the tibia and fibula may be sawn off with an ordinary saw, or

with the exsector. The line of section should be at a right-angle to the axis of the shafts of these bones, and should first remove the articular cartilage. Should the disease extend higher than this, an additional slice of bone may be removed, or any small sinuses thoroughly scraped out with Volkmann's spoon, and sponged out with 1 to 1000, sublimate. The astragalus is now removed and the upper surface of the calcaneum sawn or chiselled off, so that a smooth and freshened surface is left (Fig. 3). The

Fig. 3.

cartilage should be scraped from the posterior articular face of the scaphoid. All of the soft tissues involved in the disease should be dissected away. The os calcis and tibia are now brought together, and if the sawn surfaces fit snugly with the foot at a right-angle to the leg they are ready to be fastened.

To accomplish this, one of my drills (Fig. 4), will answer. With the foot held in proper position as above, select a drill of suitable length, attach it to the handle,

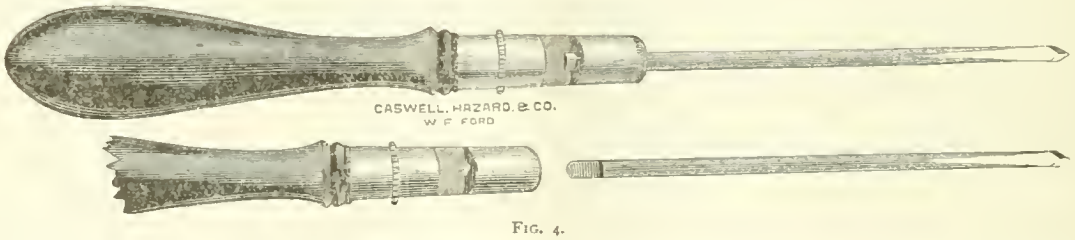

Fig. 4.

place the point one inch above the line of section of the tibia, and note how much of the drill projects below the surface of the sole, for the instrument is to go no deeper than this. With a bistoury make a small puncture through the sole, and force the drill through the calcaneum and directly up through the centre of the tibia to the depth already indicated. The handle is unshipped from the drill, which is left in position. By this method the foot is firmly fastened to the leg (Fig. 4). After securing with catgut ligatures any vessels which have been divided, a small rubber drainage-tube is inserted on either side and the wound closed with catgut sutures. A thorough and final irrigation with 1 to 3,000 sublimate follows, and a moist sublimate gauze dressing is applied with a layer of absorbent cotton and protective, held firmly in place by a gauze roller. A straight splint should be laid along the base of the leg and thigh to prevent motion. An attendant should remain by the patient until consciousness is fully restored, in order to prevent any movement that would disturb the position of the foot. In controlling bleeding, I rely almost entirely upon compression with the ordinary cheese-cloth bandage over the cotton and gauze. The foot should be kept well elevated for twelve hours after the operation. The dressing should not be opened before the third week, or later, when the drill should be removed about the thirtieth day. The drainage-tube should be gradually withdrawn—coming away entirely when the discharge ceases.

If the steel drills are not at hand a steel nail or a clean iron nail may be used, but, as in excisions at the knee, the drills will be found most suitable.

The great advantage of fixation with the drill here, as in excision of the knee-joint, is the perfect coaptation and immobility of the bones, which obviates the plaster-of-Paris dressing.

Case I.—Timothy H——, twenty-one years of age, married, laborer, Ireland, was sent to me by my friend Dr. Josephine Walter, and was admitted to Mount Sinai Hospital, August 26, 1886. Three years prior to this date, patient sprained the right ankle, which has been more or less weak and swollen ever since. A week before admission it became so painful he could not bear any weight upon the joint. He denies all venereal disease, has had rheumatism, and has the look of a tubercular patient. Appetite good; bowels regular; temperature, 99°6.

September 24th, pus was found by aspiration, and was evacuated by incision; sublimate irrigation and drainage-tube. The pus was dirty and grumous in character.

October 15, operation as above given, under other narcosis. The lower ends of the tibia and fibular were diseased, as was the astragalus. The section through the long bones entirely removed the articular cartilages. The astragalus was removed entire, and the upper surface of the os calcis chiselled off. The articular surface of the scaphoid was also scraped away. The same surfaces of the tibia and calcaneum were then united as shown in Fig. 2, and the wounds dressed as above described.

October 23d, temperature has been normal ever since the operation. November 16th, wound dressed for the first time. Tubes slightly withdrawn. Dressing again changed on November 28th, December 5th and 8th.

January 14th, 1887, patient allowed to go about on crutches. Improving. February 3d, small sinus persisting in track of one of the tubes, scraped under cocaine with Volkmonn's spoon. In April and May this was repeated, after which the wound entirely healed. At this date, October 1, 1887, the patient is entirely well, and has a sound and useful foot.

Case II.—Sophia D——, thirty-one years of age, married, housewife, United States, came under observation through the courtesy of my colleague, Professor A. R. Robinson, in June, 1885. Three months ago she had had a miscarriage, followed two days later by chills and fever, pain and swelling in right ankle-joint. Right knee also affected in same manner. The swelling in knee subsided, but that of the ankle increased, and a few weeks later, after poulticing, it opened spontaneously, discharging a good quantity of pus. A sinus persisted for some weeks, from which a thin serous fluid was discharged.

On July 6th, she was admitted to Mount Sinai Hospital. Beyond the swelling at the knee and ankle which followed the miscarriage, she had had no sickness, and gave a good family history. At this time there were two openings near the outer malleolus, through which dead bone could be felt. Joint movements painful and limited. Was put to bed with tonics and extra diet, and prepared for operation, which was done as above detailed, on July 13th. Some slight hemorrhage occurred after the patient retched, necessitating a change of the dressing and greater pressure with the bandage. The drill was not employed in this case, the bones being held in place as well as possible by the dressing and the friction box. On this account the recovery was slow, but eight months after the operation the sinuses closed, and at the end of twelve months she could bear her weight on the foot.

She is now perfectly well, uses one foot as well as the other, and has about one and a half inch shortening which is corrected by a thick cork sole.

In order to ensure success in these cases, I consider it essential that the patient should go on crutches for one year after operation, and should not be permitted to put any weight upon this side for this length of time.

Progress of Medical Science.

Hyoscyamine in Dyspnœa and Asthma.—In a communication to *The Lancet* (August 20, 1887), Dr. Walker calls attention to the action of hyoscyamine in asthma, and indeed in the treatment of spasm of involuntary muscular fibre, wherever existent—whether in the bronchi or hollow viscera (stomach, bowels, bladder). Given in the dose of half a milligramme ($\frac{1}{130}$ gr.), according to the urgency of the case, every half-hour or hour, until the spasm disappears, it is rare for the patient to be unrelieved after two or three doses. In cases of great urgency the first dose may be in the form of a hypodermic injection for quicker absorption. When relief is afforded, it may be given less frequently (two or three times a day), and gradually left off. Dr. Walker has never been disappointed with its action: it relieves the spasm promptly and efficiently, and the patient has no dread of an immediate recurrence of the dyspnœa. A young woman who is subject to occasional attacks of asthma came to him on June 7th, and was quite relieved in twenty-four hours. She did not, however, continue the remedy at longer intervals for some days, as she should have done, and so had a recurrence three weeks later. She was, however, quite cured after four or five days' treatment, and has since remained well. Her previous attacks occurred in March, 1887, May, 1886, and December, 1885, when the same treatment was equally, and as quickly, successful; so that the intervals of immunity vary from three to ten months. Dr. Walker usually gives with the hyoscyamine small doses of strychnine (the arseniate or sulphate), in half-milligramme doses, as a tonic, and to counteract the tendency to adynamy. In spasm of the stomach or bowels, in dysentery, in strangulated hernia, and in retention of urine due to spasm of neck of bladder, hyoscyamine in small and frequent doses is invaluable, and will be the first remedy thought of by anyone who once gives it a trial in these affections.

The Early Signs of Locomotor Ataxy.—Dr. Max Karger has published, as a graduation dissertation in the University of Berlin, an account of a number of observations made on 117 cases of locomotor ataxy in Professor Mendel's clinic, with the view of detecting the early symptoms of this disease; for, as he says, the great hope of a really rational and satisfactory method of treatment lies in the recognition of the existence of the disease in its earliest stages (*The Lancet*). The history given by the patients established a connection between syphilis and locomotor ataxy in fifty-three per cent. of the cases. In the earlier stages he found symptoms affecting sensation, lancinating pains, numbness, especially of the lower extremities, cord-like sensation round the waist, retardation of the rate of conduction of sensations, and, what he looks upon as especially important, being almost always present, the so-called Romberg's symptom, *i.e.*, the inability or great difficulty of balancing the body when the feet are placed parallel and close together, the eyes being shut—which, however, he does not consider is due to the ataxy, but thinks it is an abnormal condition of sensation. With regard to ophthalmic symptoms, he finds that at the commencement of locomotor ataxy there is a diminution in the acuteness of vision, and a concentric contraction of the field, amblyopia, and amaurosis, which were due in thirty-five per cent. of the cases to atrophy of the optic nerve. Then there were slight and transitory paralyses of the eye muscles. Insensibility of the pupil to light was found in sixty-six per cent. of the cases, and was due sometimes to a paralyzed condition of the sphincter, and sometimes to disturbances of reflex action. With reference to the patellar reflex, the author thinks it has been considered to be absent rather too universally. He found it in 8 of his 117 cases. The bladder reflex was often diminished, so that chronic vesical disease, the cause of which is not to be made out, ought to lead a medical man to think of tabes. Impotence was much more common than any increased sexual reflex. Very rarely gastric and cephalic crises and joint affections were noted. The author suggests that complaints of a vague nature, such as nervous pains, eye or bladder troubles, should lead the physician to make a thorough examination with special reference to the want of patellar reflex, Romberg's symptom, and the want of reaction of the pupil, as these objective signs do not necessarily give rise to any subjective symptoms.

The Recognition and Significance of Renal Albuminuria.—From a study of this somewhat hackneyed subject, Dr. Ferguson, of Troy, N. Y. (*Gaillard's Medical Journal*, September, 1887), draws the following conclusions: 1. It is usually, but not always, possible to determine whether albumen is of renal or extra-renal origin. 2. If the urine be turbid, special care by acidulation and filtration may be necessary before deciding on the presence or absence of a small quantity of albumen. 3. Negative results in acid urine, particularly when the specific gravity is low, should only be accepted as final after repeated and varied tests have been tried. 4. Heat and nitric acid, Tanret's test, and the ferrocyanide of potassium test, when it may not be convenient to apply heat, used with the precautions before noted, will usually serve all practical purposes. 5. The microscope may be necessary in differentiating the source of the albumen. 6. Cases of renal albuminuria admit the possibility of a complete recovery in a certain proportion, except chronic diffuse nephritis, in which full recovery is doubtful. 7. It is possible that other sources of turbidity are occasionally accepted as albumen, notably mucin. 8. As simple as the process of testing for albumen usually seems, it is occasionally a chemical procedure of considerable difficulty, and the published results in cases admitting of doubt only become of value when all the facts have been stated. 9. Reports of cases of functional albuminuria, in order to be of value, require special care in describing the measures used to avoid errors of observation.

Traumatic Tetanus Treated by Chloral and Bromide.—Dr. Mayer has published a case of traumatic tetanus, which he treated successfully by fifteen-grain doses of chloral hydrate and bromide of potassium, given alternately every hour for fourteen days (*The Lancet*). By that time the opisthotonos had ceased, but some rigidity of the muscles of the chin still remained. The chloral was then discontinued, the bromide being given as before for a month longer. The patient was then cured, but was too weak to resume his employment till six months later.

Gastric Movements.—Dr. Grundzach has observed some cases of catarrh of the stomach where the glandular elements were considerably atrophied, and where the gastric juice existed only in very small quantity, and contained scarcely any hydrochloric acid. Notwithstanding this, the gastric movements were normal, so that the food did not remain longer than usual in the stomach, thus proving, according to the author's views, that the acidity of the contents of the stomach is not, as many physiologists teach, the cause of the gastric movements.

The Medical Societies.—All the Medical Societies of the city are now in working order; the attendance of members is reasonably large.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, October 15, 1887.

PHOSPHORUS IN THE TREATMENT OF RACHITIS.

IT is now about four years since Kassowitz published his first report, noticed in these columns at the time, of cases of rickets treated by the exhibition of phosphorus in small doses in solution in cod-liver oil. This report was of the most encouraging nature, and, allowance being made for the enthusiasm of the writer, was apparently so conclusive of the value of this remedy as to lead many others to give it a trial in their private and hospital practice. The medical journals since that time have been filled with the reports of these experiments, and with the more or less conflicting opinions as to the efficacy of the drug in this disease.

One of the first to adopt this treatment was Guidi, of Florence, who reported a number of cases in which excellent results were obtained by the employment of phosphorus. After him came Sigel, Boas, Betz, Escherich, Hagenbach, Soltmann, Toeplitz, and many others, all of whom were loud in their praises of this mode of treatment. Petersen, of Kiel, reported upward of two hundred cases of rachitis treated with phosphorus. The cases were followed up for a long time by means of personal observations and correspondence with the parents, and in none of them did he fail to obtain a cure of the malady. Canali, of Parma, has also treated a number of cases after this plan with almost uniformly good results. The results obtained by these observers were very striking. There was a marked improvement in the general condition of the children; the diarrhœa was in many cases speedily checked, dentition was accelerated, the attacks of laryngismus stridulus became less frequent, and soon ceased entirely, the bones became firm, and the patients were soon enabled to stand erect and walk, where before their weakened limbs had refused to support them.

All the reports, however, are not of this favorable nature. Weiss, Monti, Baginsky, Torday, Schwechten and others have reported negative results, and even injurious effects from the employment of phosphorus in rickets. The unfavorable symptoms said to be caused by the administration of this drug are chiefly diarrhœa and digestive troubles. The weight of evidence, however, is thus far strongly on the side of the advocates of phosphorus.

An explanation of the want of uniformity in the results obtained may possibly be found in the difficulty of making a satisfactory and stable solution of the drug. The solution in cod-liver oil, as was first proposed, becomes worthless after it has been kept a certain time. Other menstrua which have been used do not make a perfect solution, so that at one time the patient may be taking absolutely no phosphorus, while at another he receives a dangerously-large dose of the drug, and unpleasant or even alarming symptoms are produced. Hasterlik has proposed a solution in bisulphide of carbon, which is said to be very stable and reliable. But possibly phosphide of zinc would give equally as good results as phosphorus, and, if so, it would be far preferable, since the dose could be regulated perfectly, and all sources of error and danger could be eliminated.

DAILY JOURNALISM AND SHAM INSANITY.

A USELESS and silly sensationalism seems to be a necessity of life to our great modern dailies. And nothing could be much more useless or sensational than the recent alleged attempt, under newspaper direction, of a young woman to pass herself off as insane, and get admission to the Blackwell's Island Insane Asylum. It is not at all difficult for an intelligent person to sham insanity and indigence, as this person did. She was taken to the Insane Pavilion at Bellevue, where she pretended an apathetic condition, loss of memory, and delusions of persecution. Perhaps more careful and longer watching would have detected her imposture, but it is not assumed by medical experts, at reception hospitals, that people brought there are shamming craziness, and the mistake, if it was one, in this case was natural. Indeed, if one were to go there at any time, and adhere consistently to a story of loss of memory and utter homelessness and friendlessness, there would hardly be anything else to do but commit them for further examination.

It is quite possible that an experience such as "Nellie Brown" gave herself might be made useful to the public and to the insane, if it were afterwards related truthfully and without exaggeration. But the accounts given out are, so far, sensational and grossly exaggerated, not to say actually untruthful. The Insane Pavilion at Bellevue is under the care of trained nurses, and is, we believe, conducted carefully and humanely.

THE CAUSES AND PREVENTION OF DEAF-MUTISM.

DR. A. BARKAU has published a report based upon the examination of 158 cases of deaf and dumb, and of blind inmates of the Berkeley Institution for such sufferers at Oakland. The results of his work, while coinciding in most respects with those of other investigators in this line, present some new points, which are deserving of much attention. One of the first questions studied was naturally the cause of deaf-mutism. This was inquired into with great care in 122 cases. Dr. Barkau shows that the trouble was congenital in about thirty-six per cent. of the cases, not including thirteen per cent. in which the cause was unknown, but probably dated from birth. These figures stand about half-way between Roosa's (thirty-three per cent.) and Hartmann's (sixty-five per cent.).

In 97 out of 122 cases, or eighty per cent., there was

neither ærial nor bone conduction on either side, a proportion greatly in excess of that of Dr. Roosa (sixty-two per cent.), who, however, is quoted as stating that when the patient said he felt the vibrations of the tuning it was recorded as bone conduction.

The examination of the mental capacity of the deaf and dumb showed that ninety-seven per cent. were of average or more than average development in this respect. Certainly this is a good showing for the deaf-mute class.

The hereditary or rather family element in causation was found to be an important one. In thirty-seven per cent. of cases deafness existed in some other member of the family. But direct inheritance of deafness is evidently rare (Bell's percentage was 29.5). Consanguinity did not seem to be a powerful element, there being only nine cases illustrating it. Dr. Barkau directs attention to what he regards a new observation in the etiology of congenital deaf-mutism, viz., the existence in twenty-three per cent. of cases of Hutchinson's teeth, showing, as he believes, that inherited syphilis plays a very important rôle in this matter. In Wines' table of causes syphilis is mentioned in only 2 out of 9,209 cases.

The number of originally curable cases is put down at eighteen or fifteen per cent. Dr. Barkau rightly insists upon the importance of most careful attention to patients suffering from purulent obitis occurring in scarlatina or measles. He believes, as others do, that prompt and judicious treatment of such cases by the attending physician might prevent the superventionof at least six to serious deafness. He also urges the need of specially skillful medical men to examine all cases of deaf-mutism in institutions.

ANOTHER HOSPITAL NEEDED.

It seems almost ungracious to plead for another new institution, when we consider how many have recently been established, but we cannot shut our eyes to palpable needs. The rapid growth of New York has left charity far behind, and there are large sections of the community without that hospital accommodation for which municipal aid is necessary. We have especially in mind the region above the Harlem River—the so-called annexed district. Its population is about seventy-five thousand. Its residents claim to pay nearly a million dollars in taxes and rents to the municipality every year. Yet the authorities have thus far turned a deaf ear to all appeals for at least an emergency hospital.

This district presents the usual spectacle of a growing city. New buildings are being erected, excavations and blasting are constantly going on. All these evidences of material progress mean a certain number of accidents, and those, too, of a serious nature. The nearest institution is the Harlem Hospital—on the river, at one Hundred and Twentieth Street. The surgeons here do the best they can, but the two ambulances in service are entirely inadequate to attend to the needs of the vast region. It takes often two or three hours to get a patient from the extreme limits to the hospital after the call has been received. Of course, the local physicians and the police do all in their power to aid the injured, but it has been fully demonstrated that a small receiving hospital, with a well-equipped ambulance service, is the best means for caring for the new sections of a large city. A city of seventy-five thousand people without hospital accommodations in a central locality would seem an anomaly, and yet almost this state of things exists within our own city limits.

As the city grows, its hospital centre—if we may use the phrase—is gradually creeping northward. If the present rate of increase should continue for ten years longer, there would be need of a large general hospital north of the Harlem, which should be for that region what Bellevue is to the central belt of the island now.

PHTHISIS AND THE HOUSE-FLY.

The mosquito's share in the economy of nature has always remained a mystery, except that it seems to bring out an interesting cutaneous eruption, and reduce the price of board in certain districts of New Jersey. The house-fly, however, has been credited with some general usefulness as a scavenger. This important function, if it really exists, is offset by facts now accumulating which show that the fly is, at times, a carrier of contagion.

MM. Spillmann and Haushalter, in particular, have recently shown at the Académie des Sciences, the important rôle which the house-fly may play in the dissemination of tuberculosis. The intestines of flies that have fed on phthisical sputum, and the excreta of these insects, are found to contain the bacilli of tuberculosis. Flies that have fed on such infected matter, may deposit the bacilli on windows, tables, food, and indeed, may spread potential infection everywhere throughout an apartment. When the fly dies, its body desiccates, setting the bacilli free and still capable of growth. The house-fly has thus an immortal part in the shape of pernicious microbes.

The idea that this insect may carry contagion is not a new one. The contagious ophthalmia of Egypt has been believed to be spread largely through the flies. Bacteriologists have noticed how readily cultures may become infected by flies, and Koch admits that these insects may be the vehicles for the distribution of cholera. Yellow fever has been spread, it is thought, by mosquitoes and perhaps, also, by flies.

Facts are accumulating to show that the fly may be not only an annoying but a dangerous factor in a household.

INDEX CATALOGUE OF THE LIBRARY OF THE SURGEON GENERAL'S OFFICE, U. S. ARMY. AUTHORS AND SUBJECTS. VOL. III. LEGIER - MEDICINE (NAVAL). WASHINGTON, D. C. 1887.[1]

It is perhaps only necessary to allude to the appearance of another volume of the "Index Catalogue" to bring to the minds of our readers the general character of a work which is everything that could possibly be desired in completeness and systematic arrangement. The best vindication for the existence is the fact that it is more and more appreciated as the scheme is developed and the aims of the work are elaborated. It would be more than a pity that anything should interfere with its progress toward completion. The present volume includes 13,405 author-titles, representing 5,307 volumes and 13,205 pamphlets. It also includes 12,642 subject-titles of separate books and pamphlets, and 24,174 titles of

[1] Vol. viii. of the Index Catalogue.

articles in periodicals, aggregating, we believe, a larger number of references than have appeared in any previous volume. It is a treasure to any library, and its indefatigable editor, Dr. Billings, worthily maintains his reputation.

News of the Week.

Dr. Weir's Dinner to Dr. Felix Terrier of Paris.—Dr. Robert F. Weir gave a dinner on Thursday evening, October 6th, to Dr. Felix Terrier, of Paris, the talented editor of the *Revue de Chirurgie*, and surgeon to the Hôpital Bichat. The following gentlemen were also present: Drs. H. B. Sands, T. G. Thomas, W. M. Polk, James B. Hunter, W. T. Bull, Robert Abbe, J. Magnin, and George F. Shrady.

The "Revue Internationale Scientifique et Populaire des Falsifications des Deurées Alimentaires" is the title of a new bi-monthly journal, edited by Albert de Lange, of Amsterdam, and published at Stockholm. The contents are partly in French, partly in German, and are scientific and instructive in character. It is a comment on the times, when a large and carefully edited jonral is called for, devoted to the subject of adulterations in commercial foods and drinks.

The Carcinomatous Uterus has been extirpated 60 times by Professor Fritsch, with only ten per cent of deaths; 20 patients had gone from 6 months to 7 years without recurrence.

Avulsion of the Trigeminus as a remedy for tic douloureux is strongly recommended by Mr Victor Horsley, who reports three successful cases.

A Wonderful Larynx.—The Wild West Show, in London, has been a continuous source of scientific, as well as spectacular, interest to our medical brethren abroad. The latest feature which brings out comment is the enormous vocal power of the orator, Frank Richmond, who often has made himself heard by an audience of 30,000 persons in the open air. This beats even Mr. Gladstone's record, and it is a pleasure to learn that in pure voice power America is, as usual, ahead. The *British Medical Journal* furnishes, through the help of Dr. Myles, a description of the larynx: The vocal cords are of ordinary length, and not much above the average in breadth, but the vocal processes at once strike the observer by their extraordinary development. They project inward toward the middle line like two large spurs when the glottis is open. The great leverage thus given to the laryngeal muscles allows them to act to the best advantage with a minimum of effort. The larynx itself is of a large size, and the pharynx is exceptionally roomy and well-developed, while the mucous membrane covering it is remarkably free from granulations and roughness of any kind. The "Orator's" vital capacity is not above the ordinary standard, but what breath-power he has he utilizes to the utmost with the art of a trained elocutionist.

The New York Cancer Hospital.—Two graduates in medicine, one of whom must have had a hospital service, will be appointed as house-surgeon and assistant of the New York Cancer Hospital, at Eighth Avenue and 105th Street, about December 1, 1887. The term of service of the house-surgeon will be six months, and that of the assistant one year. Apply in person to Dr. A. B. Ball, secretary, 42 West 36th Street.

Festina lente.—The Turks have a saying: "Hurry is the devil," which our esteemed contemporary, *The Lancet*, translates: "All violent or strenuous effort is bad." However put, the sentiment deserves the notice of Americans.

The Epidemic of Scarlet Fever in London continues. There were, at last reports, nineteen hundred cases in the hospitals.

Hydrophobia in Russia.—Six of the fifteen Caucasians bitten by a mad she-wolf, and for the last few weeks under treatment at the Odessa Bacteriological Hospital, have now succumbed to the disease of hydrophobia.

The Chatauqua System applied to Medicine.—Everyone knows of the success attained by the Chatauqua courses of reading. It has been proposed to adopt a similar system for the medical profession. Each member will be expected to read a certain amount each day. The books, monographs, etc., are to be carefully selected by those directing the enterprise. Such a method might stimulate study in those who are desirous to learn, but who cannot, or will not, pursue any definite methods.

The International Congress of Hygiene.—Some indication is shown of the tendency of the times in the fact that the International Congress of Hygiene just held at Vienna, was better attended than the International Congress. Early in the week, 2,400 persons had enrolled as members, and the number reached 3,000 before the congress adjoined. Distinguished men from every country were present, Virchow, Brouardel, Ludwig, Pettenkofer, Spencer Wells, Professor Humphrey being among the number.

The German Congress of Physicians and Naturalists, and Virchow's Latest Address.—According to the *Lancet* the most notable address dellivered at this Congress, which closed on September 22d, was Virchow's on "Transformismus." Its tenor may be inferred from the following brief indications. The law of heredity, in spite of all reservations, must be admitted to be universally shared by all beings endowed with life—a law on which, beyond doubt, depends the continued existence of the living world. But science will always yearn to know how life, as a whole, has originated, though attempts to satisfy this longing through the dogma of the eternity of the living world have hitherto invariably broken down. There remain only the dogma of creation and the dogma of self-production (*Urzengung*). Neither of these can be an object of research, for never yet has a living being, or even only a living element, been found of which it could be said, "This is the first of its kind." Professor Virchow proceeded to show that from whatever point the question is approached it invariably eludes the grasp. He announced himself as the friend, not the opponent, of transformism—as having at all times approached the "immortal Darwin" not aggressively, but amicably. He has always, however, observed a practical distinction between the friend and the follower. As a friend he could welcome and support a scientific hypothesis even before it has established its truth by facts;

but until these are forthcoming and conclusive he could never fall into the ranks as a follower. Whoever, he said, can teach us how to grow a "Spaltpilz" out of a "Schimmel-pilz" will have achieved more than all the heralds of the genealogical tree of man.

The Mouth contains seventeen distinct species of micro-organism, according to M. Vignal, who has of late succeeded in isolating and cultivating them, and testing their action on foods. Of these organisms, 7 dissolve cooked albumen; 5 swell it, or render it transparent; 10 dissolve fibrin; 4 render it transparent, or swell it; 9 dissolve gluten; 3 transform starch, but only 1 acts with some energy; another seems to live upon it, but without transforming it; 7 coagulate milk; 6 dissolve casein; 9 transform lactose into lactic acid; 7 intervert cane sugar; 7 cause glucose to ferment, and transform it partially into alcohol. All these actions are more or less energetic. Six of the buccal organisms were found in the fæces. Vignal concludes that micro-organisms play an important part in the digestion of food.

A Believer in Pasteur.—One of Pasteur's associates or followers was bitten by a rabid guinea-pig. He at once began a course of preventive treatment, which he continued, chiefly from motives of scientific curiosity, for more than six months. He underwent no less than 209 inoculations, without the slightest injury to his health, which is still perfect. He received 7 inoculations of 14 days; 10 of 13 days; 14 of 12 days; 12 of 11 days; 16 of 10 days; 12 of 9 days; 15 of 8 days; 12 of 7 days; 28 of 6 days; 12 of 5 days; 24 of 4 days; 6 of 3 days; 22 of 2 days; 19 of 1 day; in all, 209 inoculations, containing virus from at least 71 actively infected spinal-cords. Pasteur now writes that it is important to commence treatment as early as possible.

The Annals of Gynecology is the title of a new monthly journal, edited by Dr. E. W. Cushing, of Boston, and published in that city. The editor has secured several distinguished collaborators, and the first issue promises well.

Physicians to the Theatres.—The Municipal Government of Paris has enacted a law that all theatres shall have a physician in attendance during the time of the performance, who shall be prepared to treat any emergency. This is a very superfluous measure.

Louisville has no public medical library, a state of things which is a decided reproach to a place so justly celebrated for its medical learning and skill. A movement is on foot to start such a library, and it ought to be made to succeed.

The Pennsylvania Hospital has recently purchased about five hundred and twenty acres about twelve miles from Philadelphia, upon which it is proposed to place the insane department of the institution.

Cholera has reappeared in three cities of Chili.

Therapeutical Value of Some Recent Additions to the Genito-Urinary Pharmacopoeia.—Mr. E. Hurry Fenwick, in the *Lancet*, reports the results of three years' use of a number of new drugs. He employed them in the Out-patient Department of St. Peters' Hospital. The following are some of the notes made:

Kola (Sterculia acuminata).—A powerful stimulant; contains 2·3 per cent. of caffeine, also theobromine. In the form of chocolate I found this drug to be of great value in tertiary syphilis, where large doses of potassium iodide have to be administered. The cases of syphilis in which the chocolate was first tried were often of the worst and most neglected type, being drawn from the neighborhood of the London Docks. Later work has proved its value in the well-fed. Patients were able to take doses of thirty grains to sixty grains of the iodide without inconvenience as long as the kola was administered with it. It is now prepared in the form of a paste —"kolatina"—like cocoa paste, as it is found more effective in the liquid form. From one drachm to two drachms makes a breakfast-cupful; where this is inconvenient, the stick kola-chocolate is eaten. Dose, one drachm to two drachms.

Salix Niger (Black Willow).—A sexual sedative of decided value; useful in ovarian hyperæsthesia, also in prostatorrhœa, spermatorrhœa, excessive seminal emissions, and enforced continence. In the latter disorders its action is good, but inferior to potassium bromide. This is, however, somewhat counterbalanced by its non-depressant qualities. Dose, one-half drachm to one drachm. Finding it of value in those wearisome cases of urethral neuralgias following gonorrhœa, I began to substitute soda salicylate for it. I was impressed by the relief this latter afforded. In cases of urethral pain in the adult, I first eliminate stone, stricture, urethral granulations, and over-acid urine, and then prescribe soda salicylate five grains to eight grains, with a gratifying result.

Piché (Fabiana imbricata).—Of undoubted value in lithiasis and renal stone. One patient obtained so much relief from the hæmaturia and pain that he obtained the plant direct from Peru every mail, and made the infusion himself. In my hands it has failed in chronic cystitis. Dose, fluid extract, one-half drachm to one drachm; infusion, a wineglassful.

Papaw, *Papyotin*, *Papaine* (Carica papaya).—Of marked benefit in syphilitic ulcers of the tongue and throat, especially when mixed with cocaine. The surface of the ulcers and the white patches (secondary syphilis) rapidly clean and begin to skin over. Lozenges have been made which are most useful (papaine, one-eighth grain; cocaine, one-eighth grain; potass. bicarb., one-quarter grain). Mix papaine with a small quantity of glycerine and water, so as to form a thin paste, add a little bicarbonate of potash, and brush ulcers with the same thrice daily. Whatever its position may be, as a digestive ferment papaine is worthy of trial as a preventive and reducer (?) of renal calculi. Dose for renal stone, one grain to three grains, or more, in pill or powder; to be taken with meals.

Naphthaline ($C_{10}H_8$).—A derivative of benzol and allied to phenol. Given with benefit in fetid urine. The micrococci speedily disappear, and the urine becomes sweet. The large doses recommended (fifteen grains) are unnecessary, and produce vomiting and abdominal pain. Dose, three grains, cautiously increased. Note: Urine of patients taking naphthaline smells of phenol, and may remain exposed for some days without change.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 6, 1887.

A. Jacobi, M.D., President, in the Chair.

The Statistical Secretary, Dr. A. B. Judson, officially announced the deaths of Dr. Jared Linsly and Dr. Alonzo Clark.

The Library Committee reported large additions to the library during the summer vacation.

The President then delivered an

INTRODUCTORY ADDRESS,

in which he spoke of the continued prosperity of the Academy, the work of the sections, and the notable increase in its roll of members. He paid a worthy tribute to the memory of the late Alonzo Clark, M.D., LL.D., who was an ex-president. Reference was made to the new building for the Academy and the work of the committee, which would soon be announced in a more formal manner. The decadence of the Section on Public Hygiene was deplored, and the President thought that "an army might as well be without a flag as the Academy without a Section on Public Health." He favored the division of the Section on Obstetrics and Diseases of Women and Children, and the creation of two new sections, one on Gynecology and the other on Diseases of Children.

Dr. Frank P. Kinnicutt, on behalf of a committee of the friends of the late

THOMAS A. M'BRIDE, M.D.,

presented an excellent oil portrait of the deceased, which was accepted by the President, who returned the thanks of the Academy for the beautiful gift.

The President then presented a large number of

AUTOGRAPHS,

which he had obtained of distinguished medical men in this country, England, Germany, Italy, and France, and spoke of the desirability of like contributions for the library.

Dr. Prince A. Morrow read a paper [see page 501] on

THE MODERN METHOD OF TREATING SYPHILIS.

The discussion was opened by Dr. E. B. Bronson, who first spoke of the attractiveness of the method by hypodermatic injections of mercury, and of its advantage, especially with regard to precision of dosage. The affinity of mercury for the albuminates, however, was so great that it had been difficult to overcome, and rendered it almost impossible to introduce the remedy directly into the tissues. The method had advanced slowly, because of this difficulty, and also because of the great liability of producing local inflammatory troubles.

It was generally admitted that the mercury, in whatever form administered, finally became the bichloride. The preparation which he had used hypodermatically was the bichloride, with an equal quantity of common salt; that is, three or four grains of each dissolved in an ounce of distilled water, and the results of the method, on the whole, were satisfactory, although he was not an enthusiast concerning its employment. The great objection had been the production of local inflammatory troubles, which were liable to be prolonged. His experience in the use of calomel had been exceedingly slight.

And the results obtained by the hypodermatic method had not, in his hands, been sufficiently favorable, on the whole, to justify him in continuing it. To deposit a certain quantity of mercury in the body for the system to draw from, for the cure of a disease, seemed to him to be too commercial in character to be accepted as a rational and scientific method of treating syphilis.

Dr. R. W. Taylor began the study of the treatment of syphilis, by the hypodermatic use of mercury, in 1869, with Dr. Zinsser, who became an ardent advocate of the method, and he only ceased to practise it when he found that he was becoming the object of opprobrium among the patients who visited the public institutions with which he was connected. However, he drew the conclusion that there were some advantages in the method, and had occasionally resorted to it up to the present time, a period of eighteen years. From his experience in the use of the method during that period of time he had concluded:

1. That it was a useful method, but one of limited application. It was for emergencies rather than routine treatment.

2. That it might be used any time in the secondary period.

3. That it rapidly cured neuroses and cachexia.

4. That it had no advantages over any other method in the treatment of mucous patches, condylomata, or affections of the nervous system and bones.

5 That used at the same time with iodide of potassium internally, they were often beneficial in the tertiary stages, when the lesions were not of an ulcerative character.

6. That the method afforded the advantages of small dose, rapidity of action, and absence of systemic and local effects of mercury, such as stomatitis, diarrhœa, gastric disturbance, etc.

He believed that there was no preparation as good as a solution of the bichloride in distilled water, ten drops containing one-eighth of a grain. An injection every second day was usually sufficient. It might be pushed to one and two injections a day.

7. That the time for the disappearance of the lesions varied from two weeks to two months.

8. That relapses were as frequent, as rapid, and as severe as with any other method.

9. That it had the following objections: *a*, The injections were painful, either transitory or permanent in the form of soreness and tenderness; *b*, they produced indurated nodules, or plaques, which were sometimes chronic; *c*, they produced abscesses, which, however, might be reduced to a minimum by great care.

10. That the patients should be both intelligent, and impressed with the gravity of the disease, otherwise they would not submit to the treatment.

11. That in hospitals and dispensaries the method might be used, but otherwise frequent repetition of the injections and consequent expense were obstacles to their use.

IN THE SECONDARY PERIOD,

where rapidity of action was required, as in a case recently treated; where the healing of an initial lesion was desirable; or, where the rapid involution of secondary lesions in exposed parts was demanded, this method might be adopted. So, also, in early neuroses and cachexia.

When mercury acts as a depressant, and where its internal use, or fumigations, or inunctions were contraindicated by reason of their irritant action on the gastro-intestinal tract, mercury might be employed hypodermatically.

His experience was entirely in favor of giving the injections in the *anterior* wall of the abdomen; it was entirely inappropriate to give them in the legs.

On the whole he regarded it as a method of utility and emergency, and not one for general routine use. He regarded it as irrational to lodge purulent foci in a patient under the impression that by so doing a cure had been effected.

The bibliography of the subject, in this country, consisted of an article published by Professor Hammer, of

St. Louis, in 1867 or 1868. In 1869, Dr. Wigglesworth, of Boston, wrote on Lewin's plan. In 1871, Dr. R. W. Taylor read a paper before the New York Dermatological Society, which was published in the Medical Gazette, May 13, 1871. In 1872, a translation of Lewin's book appeared, and also in 1882, an article by Dr. J. V. Shoemaker, of Philadelphia.

Dr. F. R. Sturgis had resorted to the hypodermatic method several years ago, and used both the bichloride and calomel, and later he had employed the bichloride in albumen. His experience had been that the bichloride injections produced intense pain, abscesses, and decided discomfort for a long time. The calomel injections were less painful than the bichloride, but the effects were not so rapid and certain. From one-tenth to one-eighth of a grain he had found were larger doses than were usually necessary, and he obtained nearly as good results from smaller quantities, and they gave the patients very much less discomfort. The method undoubtedly had a decided advantage in clearing off the skin more rapidly than did other methods. According to his experience, stomatitis was not infrequent. One great obstacle to its use had been that the patients protested against the method. He did not believe that it prevented relapses more than other methods of treatment. It might be of service under certain circumstances, as, for instance, in the army and navy. But for civil service it did not present sufficient advantages to warrant its general use.

Dr. L. D. Bulkley employed the method long ago, and abandoned it, and he had not been tempted to renew it by any recent reports on the subject. He had succeeded satisfactorily in the treatment of syphilis by the use of mercury administered by the mouth, by inunction, or by fumigation, the iodide of potassium, and the necessary adjuvants, as iron, nitric acid, etc.

The President had used calomel injections, and should not do it again. Corrosive sublimate injections he had used extensively. He had found that for a large number of people, the solution of four grains to the ounce of water was too strong, and, when reduced, it had done much better.

He had used the hypodermatic method with special advantage in a particular class of cases, namely, of hereditary syphilis in which

THE CHILDREN WERE BORN WITH SCALY PALMS AND SOLES,

where it was necessary to produce as speedy effect as possible. To these children he had administered $\frac{1}{50}$ to $\frac{1}{30}$ of a grain of bichloride once a day, and he believed he had seen a number of them recover in a limited period of time.

He also spoke of the prompt benefit that can be obtained sometimes, by the free external use of iodide of potassium dissolved in glycerine or lanolin. Lanolin facilitates the entrance of the iodine, so that it can be detected in the urine within one to three hours.

Dr. Morrow said it was chiefly towards the improvement in the method that he wished to direct attention. There was no doubt of the superior efficacy of the method in accomplishing certain ends, although some of the claims made for it did not accord with his own observation. He thought there was sufficient evidence to show that mercury administered in this manner had an influence on the tertiary lesions. In cases in which the patients had an idiosyncrasy with regard to iodide of potassium, this method might be available. The value of the method was so great that no one could afford to be unfamiliar with it, and he thought that the gentlemen had made a mistake in discussing the subject in the light of observations made years ago, for the technique had greatly improved. Injections could now be made without producing abscesses; and the method could be employed without subjecting the operator to ostracism by his patients. He thought that as a general mode of treatment it was impractical; but that it was a method of remarkable efficacy.

Dr. Taylor remarked that the last time he resorted to this method was only last week, and that he did not get up to air any antediluvian experience.

Dr. Francis M. Weld's resignation was accepted, and he was made a non-resident Fellow.

The Academy then adjourned.

BRITISH MEDICAL ASSOCIATION.

(Special Report to The Medical Record.)

SECTION IN OBSTETRICS.

First Day's Session.

Dr. Arthur V. Macan, of Dublin, Master of the Rotunda Hospital, and President of the Section, made

THE ADDRESS IN OBSTETRICS.

After thanking the Section for the honor done him by electing him president, after welcoming the members to Dublin, and inviting them to make themselves at home at the Rotunda Hospital—all done in a manner and with a politeness and heartiness possible only to an Irishman—the president proceeded to tell in what ways the practice of the Rotunda Hospital differed from similar institutions elsewhere. First, the use of abdominal palpation in every case of labor, together with the practice of external version whenever necessary. Second, our time-honored, and now almost universally adopted, method of conducting the third stage of labor. Third, the application of antiseptics to midwifery. This I know has been done with success in several other places, and as it will be embraced by one of the subjects fixed on for discussion, I need not here mention it. In regard to gynecology, our practice differs from that of most of the teaching centres in this kingdom, in the systematic employment of bimanual examination, the patient lying on her back instead of on her side; the washing out and curetting of the uterus without previous dilatation of the cervix; and, lastly, the theories held as to the normal position of the uterus, and the treatment of displacements of that organ which follow.

To begin, then, with the systematic lateral palpation of the abdomen in every case of labor. There are probably few in this company who have not experienced a feeling akin to despair at the difficulties to be overcome before the child's position, even in the least complicated cases, could be determined by vaginal examination. If the labor was protracted and a caput succedaneum was formed, the diagnosis became almost impossible. I believe that a large number of even experienced practitioners used to content themselves with diagnosing whether the head presented or not, and never troubled themselves further. The position was too often that the woman was lying on her left side, the practitioner standing behind her, and the child placed upside down in the woman's abdomen. This made the mental process very complicated, so much so that the students were recommended by some text-books to cut the figure of an imaginary pelvis out of paper to assist them. All this is now changed, and any person with ordinary abilities can learn to make out the child's position after a very short apprenticeship. If, then, they are called on to deliver artificially, they can do so intelligently. We can not only make out the position of the child, but we can also generally determine whether the child be large or small, what the quantity of the liquor amnii is, and whether the birth be plural or single, and, probably the most important of all, we can determine whether the head be proportionate to the pelvis or not, by the projection of the head over the pubes, and the extent to which it can be made to enter the brim of the pelvis by firm pressure, applied externally. Finally, there is no such school for

learning the palpation of abdominal or other tumors as the palpation of the pregnant uterus.

I may mention that we can often feel the arm of the child going out from the shoulder, while occasionally the elbow may be made out. In one case a hydrocephalic head was readily distinguished, in another the probability of the fœtus being an encephalic was foretold: while in one case the cord has been felt crossing the child's back, and quite recently we have thought that we have made out the placentic site by the fingers being lifted off the child and the outlines being undeveloped.

To resume briefly, the points that can best be determined by the lateral examination are: First, the fact of pregnancy; second, the period of pregnancy; third, size of child; fourth, condition of bladder; fifth, axis of the uterus; sixth, condition of abdominal wall; seventh, abnormalities of the ovum, such as twins, hydrocephalus, anencephalus, hydatid mole, and frequently the life or death of the fœtus. Further, it directly leads to the practice of external turning, renders the finding of the fœtal heart simple, and generally enables us to estimate whether the pelvis be contracted or not. In these latter cases we also made out a low, continuous murmur like the uterine souffle, over the supposed placental site. Of course, cases in which the placenta can be palpated will always be rare. To make them possible the placenta must be planted on the anterior abdominal walls, and the condition of the wall of the uterus, etc., must be favorable to palpation.

The step from the accurate diagnosis of the position and posture of the child to external turning is an almost imperceptible one. We can sometimes turn the child by the pressure of a couple of the fingers of one hand on the head. Such cases are exceptional, however, and the difficulty gradually increases with the tension and thickness of the abdominal walls, the fixation of the presenting part in the pelvis, and the passiveness of the patient, till we come to cases when we must first mobilize the presenting part by drawing it out of the pelvis from the abdomen, or pushing it upward by the finger in the vagina; and, finally, to such cases where external turning, even under chloroform, is impossible. The cases in which we have found external turning of most importance, besides the mere rectification of a breech or transverse presentation, are cases of funis presentation, where, by turning, the funis may be carried up with the part presenting. Also, in cases of head presentation with antero-posterior contraction of the pelvis, when we wish to extract by the feet. With the head on the perineum and delayed labor, we can use a very great amount of force by pressure on the abdomen. In fact, we can get the whole weight of the body, almost, to bear on it. Suppose that much of this weight is lost by mal-direction, we still have enough to very materially aid the progress of the case and lessen the number of forceps cases. Schroeder has shown that it is want of power in the abdominal walls that delays the expulsion of the child. If the expelling force is a little less than the combined resistance, the child must, so to speak, remain forever in the same position. In such a case the addition of a single pound may be sufficient to expel the child. Further, the experience learned by palpation is a great help in the conduct of the third stage of labor. As it is much easier to rectify mal-position before strong uterine pains have set in, it is advisable for the woman to be examined some time, say a fortnight, before the estimated confinement. If a first pregnancy, we can determine not only the presentation, but also, by the degree by which the head has entered the pelvis, whether there be any disproportion or not. If there is much liquor amnii and the child is very movable, we can expect mal-position, and should watch that we have the head well into the brim before the membranes rupture. The same may be said of prolapse of the cord. Having determined the position of the child, we find the auscultation of the fœtal heart very much easier.

Next, as to the third stage of labor. As soon as the child's head is born, the hand is placed on the fundus of the uterus, the ulnar side looking toward the vertebral column, the palmar toward the axis of the uterus. The child's eyes are then carefully wiped, and a finger passed into the vagina to see if the cord could be around the child's neck. If the uterus does not expel the child, or it should make any exertion at respiration, pressure is made on the uterus which is generally sufficient to cause the expulsion of the child. This subject was discussed *in extenso*.

The following quotation explains itself:

"Following down the uterus with the hand, as the fœtus is being born, and keeping up a pressure until the placenta is expelled and the binder applied, has been the course pursued in the Dublin lying-in hospitals since the mastership of Joseph Clarke (1786-1793), and is now almost universally followed by all educated practitioners." (McClintock's edition of "Smellie's Midwifery," vol. i., p. 236.)

In looking over Dr. Charles Johnson's ward-book, bearing date of 1843, I see noted, after numerous cases, the terse statement, "placenta pressed out." This was such common practice as to need no further explanation. If we consult Spiegelberg, we will find that he accurately discriminates between the Dublin method, and the then lately introduced method of Crede, and gives his verdict entirely in favor of the former. Schroeder also accurately describes the two methods, and adopts entirely the Dublin method. We have then the curious fact that, whereas in Germany the highest authorities are in favor of the Dublin method, in the latest English text-books the writers recommend Crede's method. Or rather, I should say, while describing and recommending the Dublin method, call it Crede's. As an Irishman, and the present master of the Rotunda Hospital, I cannot but hope that, after this meeting of the British Medical Association, we may find this mistake corrected, and in the future the method may be known after the town in which it first saw light, as the "Dublin Method."

The President then devoted some few words to the bimanual examination, strongly favoring the dorsal, as compared to the lateral, position. Such assertions as that this position was brutal or indecent he strongly denied.

The subject of

THE PREVENTION OF PUERPERAL FEVER

was introduced by W. S. Playfair, M.D., F.R.C.P., LL.D., Professor of Obstetric Medicine at Kings College Hospital.

The subject which I have the honor to introduce to you for discussion cannot fail, I think, to interest all upon whom the responsibility falls of attending women in labor. The prevention of the scourge of midwifery practice, septicæmia, is one of our most important duties. In the short space of a quarter of an hour allotted me, it will be impossible to do more than lay down a few general rules which should guide us. In lying-in hospitals, since the revolution of antiseptics, a marvellous change has been effected. I am more particular today to insist on the prevention of puerperal disease in private and domiciliary practice. In the well-conducted lying-in hospital of to-day, a woman is actually as safe, if not safer, than if confined at home in a large house, and surrounded by all the comforts money can procure. The great Rotunda Hospital of this city, and the lying-in institutions of London, Paris, and St. Petersburg, as well as other continental cities, prove what I have said. There is nothing in the history of medicine more remarkable than the change in these institutions since the adoption of the

LIFE-SAVING PRINCIPLES OF LISTER.

I doubt if such a thing can be found now as a hospital for lying-in in which antiseptic rules have not been introduced, and in which similar good results have not

followed. Though recognized and followed in public practice, I doubt if, even yet, antiseptic midwifery is at all general in private practice. Called to see septic cases as a consultant, I very seldom find that the practitioner in attendance has followed out the rules in so general use in lying-in hospitals. Perhaps, when the younger class of practitioners get more into the work, it will be different, but with the bulk of men now in practice, no special care is taken. In civil practice, similar care and precautions to those practised in institutions—a matter of no real difficulty to practise—should almost wipe this scourge out of existence.

Fritsch daily dressed a putrid wound in the person of his brother for a whole year, and at the same time daily performed two or three obstetric operations, and by a vigorous antisepsis, has not had a single case of septicæmia during the whole time. To show how simply this may be done, and to elicit your views on this subject, is my object to-day. I have no time for argument, and must perforce be brief and content myself with dogmatic statements. To prevent puerperal fever we must have an intelligent idea of what it is, how it originates, and how it may be conveyed to the patient. Unless we are agreed on these points, we are not likely to come to any conclusion of value. I take it to be now almost universally admitted that puerperal septicæmia is practically the same thing as surgical septicæmia. A disease caused by a poison absorbed through the genital tract into the system, which poison may either originate *de novo* or be conveyed to the patient from without by septic matter being brought in contact with her. We should manage her so as to reduce the chance of absorption to a minimum, by closing as much as possible the channels through which the septic matter is to be absorbed by thorough and permanent contraction of the uterus, and by lessening absorptive surfaces offered by perineal lacerations and the like. How customary it is to find the binder hurriedly applied, with the uterus imperfectly contracted, remaining large and flabby underneath it, distended with clots which frequently breed mischief. I practise and teach never to remove the hand from the uterus for at least twenty minutes after the removal of the placenta, keeping up a continous, though not rough, rubbing or kneading. I believe it also good practice at this time to administer a large dose of ergot, and if contractions do not set in, to make a hypodermic injection of ergotine or ergotinine. Personally, I have never seen any harm result from the routine administration of ergot.

AS TO PERINEAL LACERATIONS,

I think the rule should be absolute that the perineum should be inspected after labor, and that every tear more than a slight laceration of the fourchette should be closed with catgut or wire suture, first cleansing thoroughly with the bichloride-of-mercury solution, and subsequently dusting with iodoform night and morning. Thus any chance of absorption through the bared perineal surface is avoided, and complete healing is insured.

Most important, however, are the

ANTISEPTIC PRECAUTIONS,

by which we are to prevent the poison being introduced from without. This, indeed, is the essence of the whole matter. The vast majority of cases of puerperal septicæmia, to my mind, arise directly from poison carried to the patient from some preventable accident. This is an unpleasant fact, but we must look unpleasant facts in the face. The nature of the medical man's work brings him constantly into contact with septic matter. There is no avoiding this. What we have to do is to take the precautions happily at our disposal to avoid the risk, or reduce it to a minimum. The obstetrician, if he has much gynecological practice, is especially in danger of infecting his patient. He has, in constant vaginal examinations, to imbue his fingers with vaginal discharges which may be of the utmost possible virulence, such as of uterine carcinoma. Many have infected themselves in this way through punctured wounds of the finger, and why not infect others?

If I dwell on unpleasant subjects such as these, my only object is to secure a thorough appreciation of their danger and its avoidance. The nurse has often, and justly too, the blame to bear. She is constantly handling the genital organs, at all hours, for many days. Many of the older class of nurses persistently set themselves against the antiseptic precautions as "new fangled fads which they don't hold with." If they are positively ordered to carry them out, they are apt to do so in the most perfunctory way. The tips of the fingers are just dipped into the antiseptic lotion. A sponge is used to wipe the genitals, and is put away, unwashed or most imperfectly washed, on a hot summer day. Quite recently I had occasion to use a catheter, and the nurse produced one belonging to her. I fished out of the eye a decomposing blood-clot which had been lying there for days or weeks. Again, not long since, I saw a most intense case of septicæmia; the nurse answered me that she had been most careful, and yet I found an undersheet unchanged for four days, saturated with decomposed lochia, on which the patient was lying. In a hundred unsuspected ways such as these death may be conveyed to the patient.

If, however, efficient antisepsis is to be carried out, the rules must be such as the nurse can understand, and not too complicated and troublesome to put into execution.

The following is a copy of the card I give every nurse in attendance on cases under my charge:

ANTISEPTIC RULES FOR MONTHLY NURSES.

"1. Two bottles are supplied to each patient. One contains a solution of perchloride of mercury, of the strength of one part to one thousand of water, tinted with litmus (called the 1 : 1,000 solution), the other carbolized oil (1 : 8).

"2. A small basin containing the 1 : 1,000 solution must always stand by the bedside of the patient, and the nurse must thoroughly rinse her hands in it every time she touches the patient in the neighborhood of the genital organs, for washing or any other purpose, before or during labor, or for a week after delivery.

"3. All sponges, vaginal and rectal pipes, catheters, etc., must be dipped in the 1 : 1,000 solution before being used. The surface of slippers, bed-pans, etc., should also be sponged with it.

"4. Vaginal pipes, enema tubes, catheters, etc., should be smeared with the carbolized oil before use.

"5. Unless express directions are given to the contrary, the vagina should be sponged twice daily after delivery with warm water, with a sufficient quantity of Condy's fluid dropped into it to give a pale pink color.

"6. All soiled linen, diapers, etc., should be immediately removed from the bedroom.

"N.B.—These rules are for the protection of the patient from the risk arising from accidental contamination of the hands, sponges, etc. It is therefore hoped that they will be faithfully and minutely adhered to."

There is nothing complex in these rules. The details may be varied considerably as to the form of antiseptic employed. It is the principle of antiseptics more than the details which is important. I prefer the perchloride of mercury to any other antiseptic, not only because of its acknowledged potency, but because it is bland and unirritating to the skin and capable of being carried in a concentrated form, and the solution made at a moment's notice. Nurses will not use a carbolic lotion, or use it inefficiently, because of its tendency to injure the hands, while I have never known one to object to the mercurial solution. I do not recommend it for vaginal injections after labor, because of a few cases of mercurial poisoning that have been reported to follow its use in this way.

There are a few precautions to be used during the labor for the physician himself:

1. Before making any examination, or using the antiseptic lotion, he should thoroughly cleanse his hands with soap and water, being specially careful about his nails, under which septic matter may easily lurk.

2. At an early stage of the labor, the vagina should once be thoroughly syringed with the antiseptic lotion, and the vulva sponged with it.

3. When the head is distending the perineum, the external genital should again be sponged with the solution.

4. Cold cream, lard, etc., should not be used for lubricating the fingers, but carbolized oil or vaseline employed instead.

5. When possible, sanitary towels should be used to receive the lochial discharges in preference to diapers, as they may be burned when soiled. All risk from imperfectly cleansed diapers is thus avoided. I do not think these suggestions impose a grievous burden upon the practitioner who has the welfare of his patient at heart. There are many other points on which I might dwell if time allowed. One which seems particularly important is the duty of satisfying ourselves of the sanitary condition of the house in which our patient is to be. It is but seldom, however, our opinion is asked on this point. Unfortunately, the public believes it is the duty of the profession to cure disease when it arises, not to prevent it. Meddling with such matters beforehand would be too often considered an unjustifiable interference. I am fully convinced that if a careful sanitary inspection were instituted before parturition, a great step would be taken toward attaining the object of this paper, "the prevention of puerperal fever."

Second Day.

Dr. Robert Barnes read a paper on the subject,

THE CAUSES, INTERNAL AND EXTERNAL, OF PUERPERAL FEVER.

A clear understanding of the nature and causes of puerperal fever is the rational antecedent of a rational system of prevention. What is puerperal fever? What are its factors and constituents?

There is not one cause, but a plexus of causes. Failure to comprehend this truth is especially conspicuous in the German school. By a short and arbitrary process of synthesis, this school has formulated the dogma that puerperal fever is puerperal septicæmia, the result of septic infection from the genital canal, thus overlooking important constituent factors. Starting from the state of gestation, we find it specially marked by exalted nervous and vascular tension. An acute process of building up is going on.

Parturition puts to the supreme test every tissue, every function. We have the combined source of altered blood: 1, That derived from gestation; 2, that arising during labor; 3, that arising from the disintegration of the superfluous tissues, built up during gestation. Labor completed, a process is started the very reverse of that which prevails in the gravida. The high vascular tension subsides. The tide turns. The blood is invaded by waste stuff which has to be cast out of the body. This is done mainly by the excreting glands; liver, kidney, skin, intestines, lungs are all called upon for active work. They must discharge the waste stuff as fast as it is received into the circulation. If this waste stuff be not duly excreted, it accumulates and acts as a fever-causing poison. Cases of thrombosis and phlegmasia dolens are mainly the expression of the loss of balance in the process of disintegration and elimination.

This is the simplest, the fundamental, form of puerperal fever, but it is the compound of three forms of altered blood: 1, The blood of the gravida; 2, the blood of the parturient; 3, the blood of the puerpera. This is purely auto-genetic. I call it endosepsis. The conditions arise entirely within the patient's system.

Another group of symptoms which disturb the orderly course of puerpera are influences which retard the secretions and excretions, as chills, malarious conditions, errors of diet, among which insufficient diet is one, bad hygeinic surroundings, and emotions.

Meteorology controls these secretions largely, and, I believe, has no little effect on the frequence of puerperal fever. I show here a number of charts. The first shows, according to the Royal Meteorological Transactions, the general temperature and rain fall for thirty years—1845 to 1874. No. 2 shows the deaths from scarlatina, fevers, erysipelas, and puerperal fevers for the same period. No. 3 shows the total births and deaths for the same period. The second series I have constructed on the same plan. It consists of the history for ten years—1875 to 1884, the months and weeks of each year are cast together so that "January" represents the sum of thirty Januaries, and each week shows the sum of thirty weeks, corresponding. In the second series we get the curves for the following ten years. The separation of ten years can be compared with the preceding thirty years. The general similarity of the curves is remarkable. It affords strong evidence of the universal prevalence of the causes. The tables exhibited showed the relation of the seasons and atmospheric conditions to fevers, puerperal and others, and illustrates a law which has been widely recognized—that zymotics are most fatal in the winter. This I believe is true. The damp from the cellars, charged, it may be, with foul water, but noxious in any case, is sure the be sucked up into the house, and seeks, by preference, the warmest spot. This is the lying-in room, the heat acting as a relative vacuum in the highly heated and poorly ventilated room. This source of danger is distinct from the ordinary drains or sewerage of the house; either may act alone, or they may act together, intensifying the danger.

This damp foul air drawn into the lying-in room may be contaminated with specific poisons, as of typhoid, scarlatina, or of erysipelas, but the contamination is not necessary to work mischief in the puerpera. This evil, that the lying-in room is chiefly supplied by air from the lower regions in winter, need hardly be felt in summer, as fresh air is brought directly from the outside. Pressure then works against the up-current, pure air is gained, foul air is repelled. (Here the author showed a model house to prevent this suction of foul air.) During the past winter, an unusually inclement one, I have been called to attend an unusual number of cases of childbed fever. I rarely failed to find sufficient cause for the trouble in the sanitation. I would enforce emphatically the old rule to move the patient to another room, preferably the drawing-room, which is generally the healthiest, most airy in the house. Sewer-gas, if not carrying zymotic germs, may cause fever. The poison, however, must be kept up. Hence the advantages gained from moving the patient out of her surrounding influences.

As to

DECOMPOSING MATTER IN THE GENITAL TRACT,

we should first close the gates against the entry of the enemy by securing firm contraction of the uterus, and prevent the suction action of the abdomen. The next step is to give ecbolics, as quinia, cinnamon, nux vomica, ergot, and digitalis. Some combination of these medicines should be given in every labor. We should then eject the enemy and prevent the gathering force by washing out the uterus. Uterine irrigation is especially useful in the auto-genetic forms in which noxious matter is taken up from the genital tract. It is not frequently necessary in the hetero-genetic or zymotic forms.

The women of the laboring classes go through childbearing more safely than their pampered and delicate sisters. It is because they are not subjected to and en-

feebled by excessive cultivation of the emotional and intellectual elements.

THE DAUGHTER OF LUXURY

never knows a day's labor till she is taken in labor; while the woman of the working classes labors every day.

Lactation is evidence of glandular capacity. Failure to produce milk, presumptive evidence of glandular incapacity. Fever prevents or diminishes secretion. In some cases, at least, failure to secrete milk is a primary, not a secondary, condition.

Fever declares itself because the glands cannot do heir duty.

From what precedes it follows, that to insure the fullest security to the puerpera, to put her in the best position to go through the transition from the puerperal to the ordinary state, we must do what we can to keep every organ, including the glandular system, in good working order; and to guard against all known agencies which may disturb the healthy action of the organs.

THE RELATIONS OF METEOROLOGY TO PUERPERAL FEVER,

is a point to which I wish to call especial attention. We see by the tables that puerperal fever, like other fevers, prevails most fatally in winter. To what extent can we control the pernicious influences of winter weather? Domestic meteorology is greatly under our control. We must inquire what are the external conditions which favor excretion. The excretory force of the lungs is increased in value in the puerpera. Under ordinary conditions, in the non-pregnant, they gave off watery vapor, carbonic acid, sometimes ammonia, and a minute quantity of organic matter. It is certain the capacity of the lungs increases after labor, so it is probable the quantity of carbonic acid exhaled is increased, and certain the exhalations of organic matter increase. The "gravis odor puerperii" is partly due to this increase. In some cases, verging closely on endosepsis, the lochial discharge is absorbed. In these I have noted a sallow aspect and a degree of febrility, and I have taken this as an indication for irrigating the cavity of the uterus.

To get rid of the excess of aqueous vapors, of carbonic acid, and organic excreta by the lungs and skin, a constant supply of pure air is required. It must be dry and comparatively rare. There are two principal modes by which gaseous matter, including germs or bacteria, are carried: 1, By diffusions; 2, by currents of air. Active diffusions are especially valuable so long as they bring nothing noxious to the patient, but if foul matter comes with the air it will tell against the case, hence the great importance of a supply of pure air, and the removal of all impediments to free circulation. I am disposed to believe the most injurious of all meteorological conditions is damp, in the forms of saturated air, fog, and mist. Wind, rain, and sun are the great purifiers of the atmosphere—movement of the air promotes diffusion, sunshine works chemical changes, and the rain scours or washes away impurities. All this, of course, is familiar knowledge, but it is not superfluous to ask if it is fairly applied to the regulation of the sick-room. Let us consider how far we may bring the meteorology of the bedroom to the conditions of healthy external meteorology. 1. Let the lying-in chamber face the south. 2. To combat external damp, a fire is best in an open fire-place, the open grate serves as a ventilator to carry off impurities. Among the abominations of self-styled sanitary engineers, I feel called upon to denounce heating by hot water pipes. They are too often effective means for the culture and diffusion of noxious germs. It is possible, also, to wash the air by air admitted by a Dobin tube, by a shower of water falling into the tubes.

The modification of the air by chemical agents, with the mechanical addition of vapors and gases possessing medical virtues, has many recommendations.

In the early morning hours, between two and four o'clock, is the time when the wind is the lowest and the meteorological conditions the worst. At this time the ventilation of the room should be attended to with greater care than usual.

All precautions resolve themselves into one word, cleanliness. All antiseptic precautions are but a part of the general scheme.

The meteorological conditions I consider to be of primary importance, though far from underestimating other causes.

While protecting the citadel from the foe without, we should take care that mutiny does not break out within.

JOHN W. BYERS, M.A., M.D. (Belfast), read on

THE PREVENTION OF PUERPERAL FEVER IN PRIVATE PRACTICE.

After giving some statistics showing the great mortality of puerperal fever, the writer said it was impossible to take measures for its prevention until we had clear ideas as to its causation. He discussed the various views, and gave his reasons for believing it was blood-poisoning, analogous to septicæmia met with in surgical practice. Taking this view, he believed there were three sources by which the poison might be introduced into the system of a lying-in woman.

1. Sewer-gas, as in unhealthy homes.
2. The nurse.
3. The accoucheur.

Under the first head, he recommended the inspection of a house before the confinement took place, to see if it was in a proper sanitary condition. He gave rules for the guidance of the practitioner and nurse. He advised the strictest cleanliness, thorough washing of the hands in an antiseptic solution (1 to 1,000 perchloride of mercury), few examinations, a proper and careful management of the third stage, the keeping of the patient on her back for a time after confinement, and antiseptic douches.

He drew attention to the cases in which a decomposing blood-clot or placenta might be the source of the disease, but believed that even in these the decomposing mass in the uterus only acted as a nidus, in which the poison from without found a suitable soil.

He discussed the question of how a physician should act with reference to obstetric practice, if he came across cases of scarlatina or foul surgical wounds, and said he believed by baths, changing the clothes, and strict antiseptic washings, he need have no fear in attending a confinement. He said if those who attended women in labor would act as if each one were likely to develop septicæmia, they would take thorough antiseptic precautions, and thus such cases would be reduced to a minimum.

The whole essence of the prevention of puerperal fever was:

1. To prevent the poison entering the system.
2. To destroy the poison, if it got into the genital tract of a patient, before it entered her tissues and blood.

DR. ROBERT BARNES, of London, said that we all agree in what Dr. Playfair has said, and it is of extreme value to us to have it put so well. It will be well for us to follow out antiseptics, but antisepsis is not the whole prevention of puerperal fever. I do not think with Dr. Playfair, that it is the same as surgical fever, but that it may also be caused by cold, chill, exposure, fever, meteorological conditions, or accidental causes. This fever is far more common in winter than in summer. There is something before septicæmia. There is a puerperal constitution which makes the poison doubly dangerous. I hope Dr. Playfair will go a little farther back and look a little at the patient.

DR. GEORGE H. KIDD, of Dublin, considered further the question of the nature of septicæmia. Dr. Burdon Sanderson has said there was a time when we were obliged to fight with all our might to make believe there was such a thing as septicæmia. This is not the trouble now. The danger is that we put too much stress on an-

tisepsis. He believes that attention to the patient previous to labor has much to do toward preventing the septicæmia. Dr. Collins, when master of the Rotunda Hospital, delivered eleven thousand women in that institution in four years, and had not one case of septicæmic fever. We must not overlook the natural history of the disease, the fact that it comes in epidemic waves.

Dr. Lombe Atthill, of Dublin, said he was a

FIRM BELIEVER IN SEPTICÆMIA.

The term puerperal fever he abhorred. It is caused by septicæmia. I was the first master in the Rotunda Hospital to require antiseptic precautions, which were then very imperfect. I had to undergo great opposition. Especially was this so with the nurses. It was indeed an effort to get them to part with their old, black, dirty dresses and put on the uniform. They thought to be compelled to wear such dresses as those in winter was nonsense. I consider a relaxed condition of the uterus to be a common cause of septicæmia. I well remember one patient who came into the Rotunda in labor. No physician was present at the time, but the nurse saw there was something the matter with her, and put her in a private ward separate from the other patients. I was soon called, and found the patient to be suffering with erysipelas. She could not be put out of the house in labor, but after delivery she was sent to another place, only remaining in the hospital fifteen hours. There had been no case of puerperal fever for months before, yet there was one before twenty-four hours, and this was followed by several others, then gradually disappearing. I think, however, these were due to atmospheric conditions, and not to the presence of the woman in the hospital. I think contamination in that case hardly possible under the conditions. I believe that the preliminary treatment of puerperal fever will prevent puerperal fever in many cases. I do not believe ergot given in a single dose will produce any effect. It should be given frequently.

Dr. M. T. Molony, Arklow, Ireland, said that in his city of six thousand inhabitants there had been an epidemic of scarlet fever for six months. During this time there was no case of puerperal fever and no approach to one. The scarlet fever was of a mild type, yet some cases were quite malignant. We had many cases of sore thorat, some of them malignant, and some tonsillitis, etc. The town is the most unsanitary place on earth. As medical officer I attended most of the cases of childbirth, and used no antiseptics.

Dr. C. H. F. Routh, of London, thought that women in an unhappy state of mind, those who had been seduced, as has been shown by Dr. Barnes, are much more likely to suffer from puerperal fever.

Dr. John W. Byers, of Belfast, was a thorough believer in the septicæmic view of puerperal fever. How can the gentlemen maintaining the views of other causes of puerperal fever explain the

RESULTS OF ANTISEPSIS IN HOSPITALS?

Our nurses should be firm believers in antisepsis. Opinion is now, I think, going in the direction that the number of cases which are auto-genetic are diminishing. The doctor then quoted from a paper by Dr. E. G. Zinke, of Cincinnati, read before the American Medical Association in 1887, and published in the New York Medical Record, where the question of "how soon after exposure to infection can you attend a woman in labor" was discussed, and the opinions of prominent authorities were quoted. These opinions were at great variance. It was a question he would wish answered.

Dr. Samuel Sloane, of Glasgow, said that antiseptics in the hospital at Glasgow, has reduced the mortality very much. They cannot do without antiseptics. We should look more to antiseptic measures than we do. I think close rooms in winter are more productive of puerperal fever than chill.

Dr. Moorman, of Edinburgh, thought the plan to stamp out puerperal septicæmia was an Utopian idea. How can we stamp out atmospheric conditions, lochial discharges, etc.? The patient should be prepared beforehand. She should be given the chloride of iron, quinine, potash, etc.; also ergot, in small doses before labor is innocuous and acts beneficially. In the prevention of puerperal septicæmia, look to the functions of the nurse more than of the doctor. It is not at all above the dignity of the obstetrician to look after the nurse. He closed by recommending uterine injections.

Mr. Lawson Tait, with Lombe Atthill,

ABHORRED THE NAME OF PUERPERAL FEVER.

The practitioners in his neighborhood had been giving him the opportunity to open the abdomen in cases of puerperal septicæmia, which operation had been followed by good results. There are two kinds—one is systemic, and medicine and surgery are powerless; the other is local, the patient can be saved. He had recently been called into the coroner's court to testify in a case where sixteen cases of puerperal fever had occurred in the practice of one man, all of which died. He inquired and found that the most elaborate antiseptic preparations had been made and carried out. He did not inquire too closely, fearing to find out too much, but after the trial, remembering that all the cases of puerperal septicæmia had been forceps cases, he asked him what precautions he had taken with his forceps. He replied none. There was the whole secret.

Dr. M. Cameron, of Glasgow, had seen five cases of puerperal septicæmia in one man's practice. He found that he had not been in the habit of disinfecting his forceps. He advised him to disinfect his forceps and burn his leather bag.

Dr. W. H. Humiston, Cleveland, O., said: If, as one gentleman has stated, puerperal fever is an epidemic disease, and occurs in waves without any assignable cause, why does it not now occur in the lying-in hospitals at Dresden, Prague, and Vienna? In these very same institutions, prior to the adoption of strict antiseptic precautions, the mortality from puerperal septicæmia was appalling, ranging from ten to eighteen per hundred.

It has been my privilege to visit these institutions, and study and observe their methods of conducting their obstetrical cases. They are most careful, and insist on the highest degree of cleanliness obtainable by frequent washing of hands and instruments with soap and water and antiseptic solutions. When Professor Leopold took charge of the Dresden lying-in hospital the mortality was eighteen per cent.; by strict antiseptic precautions it was brought down to nil, and has so remained for several years, not a case occurring within its walls.

One gentleman has asked, how soon after having come in contact with septic material is a physician justified in attending a case of obstetrics. I answer, at once, allowing time for change of clothes and thorough washing with reliable antiseptic solutions.

In Carl Brown's wards in the lying-in department of the general hospital at Vienna, the assistant has charge of the wards and takes personal charge of all complicated cases. At the same time he is daily giving operative courses upon the cadaver to students and practitioners, and I have seen him summoned from the operative table in the pathological building to make a forceps delivery. He would remove his protective coat, and go through with most careful washings of the arms and hands. I never saw septic trouble arise in cases so managed.

One important point, which is original, and I hope will be found reliable by you in your future practice, is the indication that the specific gravity of the urine gives in foreshadowing coming trouble. If before, and soon after, delivery the specific gravity of the urine is markedly below 1,020, look out for breakers ahead; for with the great amount of effete matter to be carried out of the system the urine, if the elimination be sufficient, will be of high specific gravity.

Dr. R. Y. Dill, of Belfast, advised the washing of the hands under a tap, instead of scrubbing dirt into them with a brush. Mind your nails. Always give two or three doses of ergot during the last two or three severe pains of labor. The mechanical arrangement of the beds should be such that the foot can be elevated in case of flooding and the head elevated to assist drainage of clots.

Dr. Corley, of Cork, favored the semi-erect position, but did not favor the immediate suture of the perineum.

Dr. Wallace, of Birmingham, favored antiseptics, but favored still more absolute cleanliness. He dips his forceps in boiling water and nothing further is necessary. He cleans out the uterus in the early part of the disease, and swabs it out with the tincture of iodine. As to abdominal section, when you have absolute purulent septicæmia nothing helps. When local, help can be obtained.

Dr. Shaw had practised in London for thirteen years and had 1,000 cases of labor. He never washed out a vagina, disinfected his forceps, nor lost a case from puerperal septicæmia.

Dr. A. V. Macan, of Dublin, said that we are all agreed that sepsis is a great danger after delivery. What is the relative danger of sepsis and other causes? If antisepsis reduce the cases so enormou sly the great majority must be caused by sepsis. The remainder we will present to those who think there are other causes. It is a small present. Even in the hetero-genetic sepsis must be introduced. I must say that allowing a nurse to go out to follow the calling after a three weeks' training, as is the case in London, I think to be a disgrace to civilization. Here in the Rotunda we think six months little enough.

Dr. Playfair, in closing the discussion, said: Puerperal fever was not used in the paper, yet that term was heard again and again in the discussion. Cold and chill may produce a puerperal disease, but not puerperal septicæmia. No one is more fully possessed than I with the idea of preparing a patient against puerperal septicæmia. As I said, my allotted time was far too brief to allow me to go over the whole ground; I must omit something. I think there never was an epidemic of puerperal septicæmia; it does not come in this way. It is totally different from cholera and that class of diseases. This is a most dangerous theory. Puerperal septicæmia may be introduced through the atmosphere. The statement of Dr. Humiston is one of the most remarkable statements I ever heard. That the assistant can, and does, do this goes to show what can be done by antisepsis. This would be dangerous teaching, however, because others might not carry out the antiseptic precautions properly and thus do much harm.

Dr. G. Apostoli, of Paris, France, read a paper on

his treatment of fibroid tumors of the uterus by electricity, with complete statistics of all cases treated from July, 1882, to July, 1887.

Dr. Routh, of London, said he felt greatly interested in Dr. Apostoli's paper, especially after seeing his demonstration that morning. It was a method he himself had applied with success, but that success was not constant, and the wounds made were sometimes troublesome to heal. The use of potter's clay and the galvanometer, as devised by Dr. Apostoli, put the whole process on a different basis, and entitled him to the highest praise.

About 1850 he had tried electricity on a case of painful induration of the breast occurring in a lady at the menopause, whose mother had died a year or two before of cancer of the breast. There was also cancer in other branches of the family. He placed an exactly fitting plate of copper on one breast and one of zinc on the other breast, both being covered with lint dipped in a strong solution of vinegar. After two or three months the tumor disappeared and that patient is now alive and well, though over eighty years of age. He did not say it was cancer, but it looked very like it. He had used it on two other women while physician to the Samaritan Hospital in London. In one the tumor was as large as a child's head, in the other as large as a *man's* head. The sound was placed in the cavity of the uterus, the vaginal portion being isolated. A large wet pad, consisting of metal covered with lint, was placed in one case on the belly, in the other on the back, and severally connected with a powerful Daniel battery, which was used in the hospital for actual cauterization. In both wounds were made which were long healing, but both tumors disappeared; one he saw a year after, the tumor being about the size of a mandarin orange. In the other no trace of tumor existed.

Now, Dr. Apostoli stated that in his process the time of operation should be limited to five or ten minutes, and that it was not to be carried to the extent of giving pain. Dr. Routh had found, with English women at least, that if inspired with any prospect of success, they were quite willing, nay, even desirous of having it to the fullest extent, and he had kept them repeatedly with active suffering from twenty minutes to half an hour at a time. Where would be the disadvantage in so doing if the patient was willing and if thereby were certainty of cure?

Again, Dr. Routh wished to know what plan Dr. Apostoli would follow in cases of extra-uterine fibroids, especially if attached to a pedicle. He had not ventured to apply puncture here, as several Americans had done, because some deaths had occurred.

Lastly, Dr. Apostoli had stated that it was not desirable to apply a current so strong that it caused the tumor to move. Now, Dr. Routh had used it to that extent, and it was a source of great joy to the patients, as they saw and felt that a large tumor, fixed and heavy, had become smaller and mobile, and so justified their satisfaction.

The battery he had used acted differently in the same person at different times, sometimes producing great pain with few cells, sometimes none with very many. He would wish to know if this was due to a penchant of the patient, or to a difference of power in the action of the battery.

Dr. Playfair, of London, had no doubt that we had in this mode of treatment great possibilities. As to its hæmostatic properties, I am absolutely satisfied. I have tried it on two cases at Kings College, and with good results. In one of them, a hæmophilic, who had been bleeding from the uterus fourteen days out of every twenty-eight, I gave her three sittings previous to her last expected period, and it lasted but four days. In the other case, of bleeding fibroid, the result has been quite favorable.

Sir Spencer Wells also spoke favorably of the treatment, and related what he had seen at Apostoli's clinic. He saw one hundred women several months or a year after treatment; saw and heard from their own lips of their improvement. Not one complained of pain or discomfort. The health improved, and I saw on the disappearance of the tumor the deposit of fat take place.

Dr. William Duncan, of London, had treated numbers of cases after this method in Middlesex Hospital, where they have abundant electrical apparatus. He reported the case of a young girl who came in blanched with bleeding from a fibroid, and was saved by Apostoli's method. He thought the abdominal electrode of potter's clay rather mussy and awkward. He had tried one of several thicknesses of blotting-paper, but found the patient could bear but 150 milliemperes, which gave excessive irritation and redness to the abdominal wall. The same patient could bear 500 with the potter's clay, and have no irritation. The great point is that we can use such an exact measurement. We should not go too strong. The report from America of the use of 1,008 milliemperes I think is false.

Dr. W. E. Stevenson, of London, had his electrodes made of platinum. In 1883 he had great difficulty to get practitioners to send him patients. Dr. Apostoli has popularized the treatment to such an extent that we now

get many cases. I am using it with good results in St. Bartholomew's Hospital. I have used the steel needles of which Apostoli speaks. I think it impossible to use 1,000 milliemperes as reported from America. I have to thank Apostoli for the potter's clay electrodes, by which we are able to use much higher power.

Dr. Skene Keith, of Edinburgh, reported his experience. His results were quite good, but time enough had not yet elapsed to know whether or not they were permanent. He had visited Apostoli at Paris, and found much of interest and benefit there. In one case, a woman aged sixty, tumor no smaller in March and June than for years before. Five applications after Apostoli's puncture, brought the tumor from a probable eighteen or twenty pounds to a probable twelve pounds. In a second case, after two applications without puncture, a young woman felt much better, when the treatment was obliged to be discontinued. Third case in a bad condition, but now much improved. We have eleven cases of fibroid tumors now, and fourteen other cases in all; we have made one hundred and twenty applications, and had no bad results. I hope this system has rid us of an operation I am not at all sorry to part with.

Dr. Macan, of Dublin, thought if the results can be obtained without a most fatal operation, we are all to be congratulated. The treatment is more applicable to persons of long purses, as it must continue over a considerable period.

He was quite struck this morning with the exhibition at the Rotunda by Dr. Apostoli of his treatment. It will be repeated to-morrow.

Dr. M. Q. McCallahan, of Brailsford, read a paper on

A MONTH'S ABDOMINAL SECTIONS BY MR. LAWSON TAIT.

This consisted of a brief report of thirty-five abdominal sections—of course all recovering, some of them almost snatched from the other world. Several were for septicæmia.

Mr. Tait, who was present, said that the reports just read would show how he selected his cases. This cry about the selection of cases is an absolute falsehood. I care not who says it. One case reported here was one I would certainly have been excused from operating. The woman was brought in, in a state of collapse, almost dead. I had done three hundred laparotomies with but two deaths, and I did not care, I assure you, to add another. I confess it was a temptation to refuse, but I thought I must give the woman a chance for her life, slight as it might be. The result was wonderful. Suppose some of our

"TRAMP VISITORS"

had come along and seen this case. He would have gone away saying, "Lawson Tait is the most reckless operator I ever saw."

Dr. Robert Barnes, of London, expressed unqualified admiration of Mr. Tait and his results. He thought the surgery of the abdomen and the brain were epochs in surgery. He was glad to know that they were British productions, and that we are not indebted for them to the Germans.

Dr. W. H. Humiston, of Cleveland, O., said he was one of those "tramp visitors" who was excluded by Mr. Tait. He had heard Mr. Tait abused and called a liar in Germany, but it was done by those "tramp visitors," scamps, and scalawags, who went once or twice, and went away to criticise. If you want to study a man's methods go and stay long enough to know something about them.

Mr. Tait: The "tramp" does mischief in more ways than one, and

I'LL 'AVE NOTHING MORE TO DO WITH HIM.

He is doing mischief on the other side of the Atlantic. There are two kinds of doctors in America as well as in England. Some know something, others do not. I have had doctors come from America, bring their wives and families, and stay six months. I taught them all I could. Others came once or twice, went away, and knew more than those who had been there six months.

No case of puerperal peritonitis ought to be left to die without the abdomen being opened, and I believe the day will come when we will make a large number of operations in the median line for hernia.

Several other speeches laudatory of Mr. Tait and his methods were made. The speakers all expressed faith, hope, and charity.

Dr. Murdoch Cameron (Glasgow) read a paper on "The Pathology of Abortion;" Dr. T. More Madden (Dublin) on "The Treatment of some Forms of Sterility;" Dr. W. J. Smyly (Dublin) on "The Diagnosis and Treatment of Diseases of the Endometrium;" Dr. Robert Barnes (London) on "The Theory and Treatment of Placenta Prævia." Several other papers were read by title; the session having devoted the most of its time to the papers on the first part of the programme.

Session adjourned.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 25 to October 1, 1887.

Smith, A. K., Lieutenant-Colonel and Surgeon. Granted leave of absence for one month and fourteen days, to take effect upon his being relieved from duty at U. S. Military Academy. S. O. 223, A. G. O., September 24, 1887.

Johnson, R. W., Captain and Assistant Surgeon. Granted leave of absence for twenty-one days, to be taken advantage of so that he will return to his station at latest by the middle of October, 1887. S. O. 204, Division of the Atlantic, September 23, 1887.

Duty, W. D., First Lieutenant and Assistant Surgeon. Leave of absence extended one month. S. O. 223, A. G. O., September 24, 1887.

Knudler, William L., First Lieutenant and Assistant Surgeon. Ordered to accompany Light Battery F, Fourth Artillery, from Fort Snelling, Minn., to the International Military Encampment at Chicago, Ill. S. O. 97, Department of Dakota, September 20, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 1, 1887.

Means, V. C. B., Assistant Surgeon. Ordered for examination preliminary to promotion.

Derr, E. Z., Passed Assistant Surgeon. Detached from Navy Yard, New York, and ordered to the Nipsic.

Ashbridge, Richard, Passed Assistant Surgeon. Detached from Naval Academy, Annapolis, Md., and wait orders.

Russell, A. H., Passed Assistant Surgeon. Ordered to the Naval Academy, Annapolis, Md.

Herndon, C. G., Passed Assistant Surgeon. Detached from Naval Dispensary, Washington, D. C., and ordered to the Enterprise.

Arthur, George, Passed Assistant Surgeon. Detached from the Museum of Hygiene, Washington, D. C., and ordered to the Naval Dispensary.

Griffiths, S. H., Passed Assistant Surgeon. Ordered to the Museum of Hygiene, Washington, D. C.

Spear, J. C., Medical Inspector. Leave of absence granted until July 1, 1888, with permission to leave the United States.

Medical Items.

The Two Aspects of Phthisis.—In dealing with phthisis we are always prone to regard it mainly either as a true lung-disease or as a constitutional malady, with a pulmonary lesion as its most constant, and usually most important, local expression. The former is the tendency of the student and young practitioner, who are apt to think that through the stethoscope may be learnt most of what is worth knowing about the disease; the latter becomes more and more the view which arises from a wide experience of phthisis, and gradually impresses itself upon us as vitally important, especially with regard to prognosis and treatment. Dr. H. G. Sutton puts this strikingly in his recently published and profoundly suggestive lectures on "Medical Pathology." He says: "In considering phthisis and the treatment of phthisis, do not think of the lungs so much, for it is simply harassing to one's self, and leads to the death of the patient, and no one benefits by it. How can a lung be repaired if there is not sufficient blood going through it? The one object in the treatment of phthisis is to get more blood through the lung to repair it; hence the importance of rest, food, and fresh air." All the main principles in the treatment of phthisis now generally adopted, namely, liberal dietary, tonics, open-air life, change of climate, etc., aim at the improvement of the constitutional condition; the assumption underlying these measures being either that the local condition is inaccessible to therapeutics, or else that it may be confidently expected to improve with the improvement in the organism generally. No doubt since the discoveries of Koch, patient and enterprising efforts have been made to strike at the real origin of the disease by measures directed to the destruction of the tubercle-bacillus. Hence has arisen the wide adoption of antiseptic inhalations, and more recently the injection of sulphuretted hydrogen, carbonic-acid gas, etc. Without seeking to prejudge the results of experiments still in progress, it must, we think, be owned that the net result of this local therapeusis in phthisis has hitherto been very small. Inhalations do good unquestionably, but in what class of cases? Chiefly in old cavities filled with putrid secretion, where the *rationale* of their action is too obvious to require demonstration; but we are still without evidence of their utility in incipient phthisis; in other words, their influence in checking the development or limiting the activity of the bacillus is still an unproved hypothesis. It is to be feared that Koch's discovery, whatever may prove its ultimate value, has done mischief in the department of therapeutics by tending to obscure the view put forward so bluntly and yet so truly by Dr. Sutton, that in the treatment of phthisis we should think of the organism, and not of a single organ. Local measures of another kind have had a wide popularity and a certain utility in phthisis. We refer to counter-irritants, the efficacy of which has been particularly insisted upon by Professor Jaccoud. No one can try them patiently without being convinced of the resulting benefit. They relieve cough, and enable us to dispense with anodynes, but it seems doubtful whether they have any other beneficial action whatever. Many years ago it was proposed to treat early cases of phthisis by strapping the apex, after the fashion adopted so usefully in pleurisy. It may be doubted whether this practice is now ever adopted, and there can hardly be a doubt that the proposal was based upon a radical misconception of the nature and requirements of the disease. All our knowledge now tends to show that phthisis arises from inactivity and not from over-action of the lungs; and so far from endeavoring to limit the play of pulmonary function, one of our chief aims, apart from the actual presence of hemorrhage, is to promote it. While the constitutional view of phthisis is, for the present at least, much the more useful with a view to treatment, Dr. Sutton would, no doubt, be the last to deny the indispensable value of a correct estimate of the local signs. Especially is this so in diagnosis. We may strongly suspect the existence of phthisis before the lungs yield any sign, but we can hardly get beyond the point of mere suspicion. Asthenia, emaciation, night-sweats, and febrile disturbance may combine, with a bad family history, to make us view a case with the gravest anxiety, although the stethoscope yield no abnormal indications; but, while the lungs remain free, we always continue to hope that our suspicions may prove unfounded. Again, the extent of the local lesion is always a very vital point. A patient with a cavity in one apex, while the rest of his lungs is sound, is in a very different position from one in whom we find evidence of disseminated tubercle throughout a large area of the pulmonary substance. The progress of the local lesion, which only local investigation can determine, is also a point of cardinal importance. There is the most radical difference between a case of phthisis in which the local signs remain quiescent for months or years, and one in which they creep steadily onward. The former case allows an opportunity for treatment, and permits a more or less favorable prognosis; the latter case is sure soon to terminate fatally. It is evident that in phthisis it is essential that the relation of the local and the constitutional condition be correctly estimated and steadily kept in view.—*The British Medical Journal.*

Dangers Attending the Oertel Treatment of Obesity.—Professor Rosenfeld (*St. Petersburger Med. Wochenschrift*) argues that Oertel's method of treating obesity is not without danger. The deprivation of liquids tends to augment the relative quantity of uric acid excreted, and thereby may provoke parenchymatous nephritis, with albuminuria. Strict supervision is, he thinks, always necessary. Directions relative to mountain-climbing and to abstention from liquids ought to be followed with prudence by persons whose habits have previously been opposed to this regimen; they should cease the treatment immediately upon the appearance of dyspnœa, vertigo, and other symptoms indicative of cardiac incapacity. The attention of the physician ought to be directed to the heart, the stomach, and the urine.

Precocious Children.—The precocious child is constantly saying things so epigrammatic and brilliant as to call out the wonder of admiring parents and relations; and oftentimes these strange, unnatural utterances are made the subject of remark in the presence of the child, and some newspapers often devote a column to this bright and abnormal child-talk. Nothing could be more harmful than such encouragement of a condition that is out of all harmony with healthful mental and physical growth. As a rule, the precocious child is of a strumous or scrofulous diathesis, with a fair, brilliant complexion, blue eyes, and golden hair, beautiful to look upon according to popular standards. He is delicately sensitive to mental impressions, and alive to the conversation of persons much older than he. He generally goes on in his unique career, outstripping his brothers and sisters, as well as his schoolmates, in the committing of tasks at school, as well as in the reading of books far beyond their comprehension. This generally goes on until the age of puberty, when he begins to falter. The hectic flush is seen upon the fair cheek, the eye becomes more brilliant, and the finer and the spiritual elements come out with almost supernatural intensity. By and by a slight cough arrests the attention; and, before the fond parent is aware, phthisis tuberculosis has laid the foundation for premature death. Now, what shall be done to save such children, and make them develop into healthy men and women? First, we would say, Let them severely alone. By this we mean, do not encourage the precocious development by pushing the child ahead and showing the foolish weakness of exhibiting the child to visitors, or displaying him at the performances of Sunday-school concert or public-school exhibitions.

We always pity the poor victims of such scenes, who come before audiences and recite standard poems or sing *cavatinas* to astonished crowds in heated rooms, amid the glare of gas-lights and dressed in tawdy finery, irrespective of the climate or weather. When we look upon their pale faces and attenuated legs, we wish we had the power to send them home and put them to bed. Second, be simple with such children; keep them young, and encourage them to talk child-talk, to read child-books, and to play with other children. Do not let them remain in the house in company with the older folk, when the bright sun is shining, and the other children are romping upon the green with all the glorious freedom of childhood. Of paramount importance is the physical training of the precocious child. From the very nature of the case, all undue excitement must be avoided. The full quota of sleep must be insisted upon. No late hours should be allowed, full of the amusements that are such a strain upon the nervous system. The diet should be of the simplest character, consisting of food containing all the elements of nutrition, like milk, bread, and soups. Confections, condiments, and fancy dishes should never be set before children. Give fresh air in abundance, and insure the child to go out of doors in all kinds of weather.—*Popular Science Monthly.*

Differential Diagnosis of Ulcers of the Face —

LUPUS.	RODENT ULCER.	EPITHELIOMA.	SYPHILIS.	STRUMA
In young people.	In elderly patients.	In adult life.	In children.	In children.
Attacks skin of ala of nose.	Favorite position—the skin of lower eyelid.	Attacks junction of skin and mucous membrane—lips, nose, eyelids.	Affects corners of mouth and margins of nose with deep scars.	Superficial eczematous ulceration, with crusting on lips and nose, leaving no scars behind.
Commences in a discolored tubercle.	Commences often in a brown horny patch.	Commences as a small, irregular tubercle.	Commences often in vesicles or blebs.	
Ulceration superficial and slowly spreading across the cheeks, healing at one part and breaking down at another.	Spreads steadily with no induration. No tendency to heal.	Infiltrates from first and extends rapidly.	In adults. Superficial, more or less circular multiple ulcers about any part of face, with scars of healed ones; or, deep, unhealthy cavities from breaking down of gummata.	
No glandular affection.	No glandular affection.	Glands involved		
Not usually painful.	Not painful.	Painful.		

Christopher Heath, London.

A Discussion on Pachydermia Laryngis, at the Berlin Medical Society, took place on July 27th. Professor Virchow said that his researches and those of Rainer had shown that there is a certain analogy between the mucous membrane of the larynx and the skin, and there are therefore diseases of this region which have great similarity to diseases of the skin. Two processes must be differentiated: one of them affects the mucous tissues mostly; the other, the epithelium, and renders it similar to a thin skin. Both diseases are chronic inflammatory processes. The latter was called by Virchow, *pachydermia.* There are two kinds of pachydermia, the *diffusa* and the *verrucosa.* The parts most liable to diffuse swellings are those where there is not so much connective tissue, especially the processus vocales of the arytænoid cartilages. Here frequently occur swelling and epidermic hypertrophies which may be looked upon as cancerous. It is not right to call such neoplasms "papillomata;" they must be called epitheliomata, and a distinction must be made between *hyperplastic* and *heteroplastic* epitheliomata. The microscopical difference between these forms is often difficult, and is dependent on the nature of the basis of the neoplasm. If in the basis is epithelium, especially of alveolar structure, there is a carcinoma; but if the basis is of normal structure, the neoplasm is benign, and the same if the surface is covered with papillæ. Such papillary growths are found not only on the vocal bands, but also in the interarytænoideal space, the epiglottis, and also on the pharynx and uvula. Such growths must not be viewed as fibromata. Virchow illustrated his lecture with specimens and sketches. Such growths can easily recur, but it must be allowed that by energetic treatment they can be finally perfectly destroyed. They can also disappear as spontaneously as cutaneous warts will do. Waldeyer could positively state that wherever there is a pavement epithelium there are also papillæ, and he does not believe that the epithelial growths occur without papillary growths also. Virchow stated that in his case he had not seen papillæ. Waldeyer maintained that very much depended on the direction of the cut. If it is parallel to the vocal bands, it can easily be between the papillæ; but if it is a cross direction they are always seen. Lewin agreed that he always found pavement epithelium combined with papillæ.

Salicylate of Soda in Whooping-cough and Migraine.—The remedies recommended for the treatment of whooping-cough are as varied as they are generally unsuccessful. However, to the long series another has been added, which we are assured gives speedy relief. The remedy in question is salicylate of soda. Forty grains are given in three or four doses in the afternoon, with the result that the fits of coughing diminish rapidly, and vomiting disappears altogether. I have never tried salicylate of soda in such cases, so I cannot vouch for the benefit that might be derived from it, but for migraine or sick nervous headache, salicylate of soda is an absolute specific. Its action is very speedy, for one hour after taking it all trace of pain is gone, so that persons who are habitually laid aside for the whole day with migraine, and only finding relief in a prolonged sleep, can be sure of being quit of it in the early morning, and consequently the mid-day meal can be thoroughly enjoyed, and business pursuits can be as freely as ever indulged in. The dose is twenty grains in a little peppermint-water on rising, or when the pain commences, and in half an hour after a similar amount. At the end of an hour, as I have already said, the pain has disappeared completely. — Dr. Hastings Burroughs, *Providence Medical Journal.*

Bone Hemorrhoids.—Under this title a correspondent of the *Cincinnati Lancet-Clinic* reports the following suggestive case: Mrs. H. had been suffering for a great many weeks from a lateral swelling of the rectum, which gave her severe pain continuously, and was highly augmented during the act of defection. She applied to a prominent specialist for examination. He promptly diagnosed hemorrhoids, and instituted treatment by injections which he gave fortnightly for a period of two or three months without benefit. The patient becoming discouraged, applied to another specialist for treatment, whose diagnosis was the same as that of Specialist No. 1. After first treatment from Specialist No. 2, the pain became so severe that she was obliged to resort to means of relief to reduce it. Accordingly, he was called, the specialist not being at hand, and made an examination, and found protruding from the right side of the rectum a tumor conical in shape and livid in color, and very sensitive—indeed, so much so that the least touch would cause her to scream and writhe with pain. In the centre of the cone-shaped extremity of the protuberance was an aperture from which pus was discharging very scantily. After painting the region with four-per-cent. solution of muriate of cocaine every two or three minutes for a quarter of an hour, he introduced a probe, and without difficulty came upon a hard substance, which upon being extracted proved to be a beef-bone, pyramidal in shape, about one inch long and three quarters of an inch wide at the widest part. The patient made a complete recovery within two or three days, with only one treatment, "without severe pain, knife, or ligature."

The Proper Method of Examining the Breast.—Dr. Gross says that to examine properly a woman's breast, she should be lying on her back. If examined in other position, it can be so manipulated as to convert it into any tumor. When on her back, examine by pressing the tips of fingers back through the breast against the chest-walls, and not by pinching the structures up between the fingers.—*College and Clinical Record.*

Original Articles.

A PHYSIOLOGICAL BASIS FOR AN IMPROVED CARDIAC PATHOLOGY.[1]

BY T. WESLEY MILLS, M.A., M.D.,

PROFESSOR OF PHYSIOLOGY IN M'GILL UNIVERSITY, MONTREAL.

I.

AFTER having been engaged for some years past in continuous investigation of the physiology of the hearts of animals, it occurred to me to inquire what new light these investigations, and those of others of a similar kind, might throw on the pathology of cardiac disease. On comparing the best articles of recent date in standard works, and also recent utterances in the form of special courses of lectures, I became satisfied that a conviction, deepened more and more during the course of my investigations, was well founded, viz.: That with our present physiological knowledge, the usual explanations of pathological conditions of the heart are too *mechanical*. This has probably to be credited to physiology, however; for with the progress made in experiment by means of complicated apparatus, we seem to have got into a mechanical way of viewing physiological processes; in other words, our thought smacks of the workshop—the laboratory. But nature refuses to be interpreted by any one rigid method. To have a just idea of her *modus operandi* in an organism we must combine all possible methods of observation, and even then humbly admit that we see but a small portion of the truth. But in asking the reader to consider what I have to present, it is but right that I should not only give him the grounds on which my opinions are based as evidence, which he can weigh for himself, but that I should candidly tell him of the paths I have been treading, and leave him then to judge of the value of the opinions advanced. Well, then, during the past three years I have studied, by the comparative method, the hearts of the water-tortoise, the sea-turtle, the alligator, the fish, menobranchus, and the snake. The safe method of direct observation with the use of simple apparatus has been employed, and the heart has in all cases been left *in situ* and kept in good condition as to nutrition, or the relation between the latter and the result has been noted. These methods are not the ones most fashionable with physiologists at the present day; they are very laborious and time-consuming, but, in my opinion, they give results which, so far as they go, are reliable; and they teach a thousand things which to the physician are fraught with instruction. One's opinions on any subject are determined not alone by what he can clearly put into words, but also by much that only the individual immediately engaged can ever appreciate; and the value of conclusions, therefore, must always depend a good deal upon the mind that forms them, as well as the methods by which they are reached. I shall, then, in this paper, endeavor to give a basis for the views I advance, at once clinical,[2] pathological, and physiological, or, in some instances, rather biological. It will be borne in mind that almost all the knowledge which I purpose to use, so far as the cardiac nerves themselves are concerned, has accrued from the investigations of the last half-dozen years, and especially the last three or four. I propose, in this paper, to attempt to substitute for mechanical explanations as applied to cardiac pathology, neuro-trophic ones; to show that what has in many cases been denominated the cause of such and such an affection, has really only been the *occasion*. It will be impossible to cover the whole ground of cardiac pathology, so I must endeavor to make the character of the explanations I would apply, clear, rather than to furnish detailed solutions for each case.

It will be found that writers on cardiac diseases have been accustomed to lay great stress on sexual excess as a causative factor in various affections, including the so-called irritable heart; and many writers[1] are of opinion that "heart-strain" is a real cause of break-down in athletes; but explanations of this result are either wholly wanting or are mostly of that mechanical kind, the validity of which I shall call in question. I have not the least doubt that these views, as to the actual connection of break-down with the factors associated with it, are correct in fact: and the explanation I would submit is to this effect: In every living organism there is a possible maximum of vital force. In organisms with a nervous system there is a certain similar maximum of available nervous energy; the amount depending on the condition of the animal at the time—just as with a Daniell's cell there is only so much electricity generated, even when in the best possible condition—which may be very much less if the conditions of the battery's action are not perfect. If a portion of this electric force be diverted along one conductor, there is so much less left for other possible channels; thus it is with the nervous system. To apply this, first, to sexual excesses and their consequent effects on the organism, the heart included.

When the sexual orgasm—well so called—is regarded physiologically, it is seen to involve the most violent discharge of nerve-force that ever takes place in a normal animal. It is, in fact, comparable to a pathological convulsion. It is physiologically justifiable only when there is a surplus of nerve-force; and then it may produce that equipoise of forces after which nature seems everywhere to be striving. But except under these conditions it is a drain upon the store of vital force incomparably the greatest known to us. What happens in the oft-repeated sexual act is well illustrated by the functional action of electric fishes. The electric discharge is correlated in these animals with a corresponding nervous discharge, the physiological relations of which are now well understood. But after a certain number of discharges and in a very short space of time the fish is exhausted, and requires rest before there can be a functional repetition. Sexual excess implies that there is loss upon loss. It remains now to show how this is related to enfeeblement and disease in organs distant from the nervous system.

I propose to attempt to show that there is *continually* flowing out from the nervous centres, along the nerves, influences *essential* for the nutrition of the tissues: and that every functional act implies a corresponding nervous outflow, not only as a part of the connected chain of events for the manifestation of that function, but for the

[1] Read in abstract at the meeting of the Canadian Medical Association, August 31, 1887.

[2] Unless otherwise announced, my authority for clinical and pathological statements will be the articles on cardiac diseases in the Am. System of Medicine (Pepper), in the first series of which, especially, there is a determined effort evidenced to place the views advanced upon as good a physiological basis as the knowledge then available permitted.

[1] Am. Syst. of Med., vol. iii., p. 629 et al.

actual healthy nutrition of any tissue to which nerves are supplied. I propose to go further, and show that the functional action of a tissue (*i.e.*, an aggregation of cells) is but one of a series of changes which are closely bound up, if not identical, with the nutrition of that tissue.

The meaning of this will be clearer after the citation of a few facts—clinical, pathological, and physiological. That constant worry, grief, and the whole class of depressing emotions are associated with impaired appetite and nutrition is a matter of the commonest observation; and that the opposite class of emotions leads to contrary effects is equally well known. But what has not been at all clear is the *rationale* of this really wonderful connection.

Both pathology and physiology assist in the explanation. The most remarkable results have followed the secondary suture of nerves, accidentally divided long before. Thus in a case in the Montreal General Hospital, in which Roddick[1] sutured the sciatic nerve that had been divided seventeen months previously, the healing of two troublesome ulcers followed immediately. To what else could this possibly be due, if not to influences passing along nerves from centres of nerve-force—we might say, of vital force? Such cases make more clearly, perhaps, for the view I am advocating than others in which the anatomical pathological changes in the nerve-centres have been well known.[2] The dependence of paralysis on localized central nervous changes has long been recognized, though the meaning of the connection has not been hitherto clearly pointed out. The fact that in some forms of paralysis (hysterical) there is not wasting, goes far to establish the view I entertain of a nutritive influence *constantly* passing along nerves. A skeletal muscle degenerates after section of its nerves; and if the result is delayed when electricity is used, it is, I would suggest, because this agent simulates nerve-action, though imperfectly. There are physiological experiments which are more definite if not more convincing than the pathological evidence. Bernard,[3] more than twenty years ago, and Heidenhain[4] somewhat later, showed that, after section of the nerves of the salivary glands, a flow of saliva followed, which soon reached a maximum, and declined as regeneration of the nerves took place. This so-called "paralytic" flow of saliva is not an evidence that secretion is independent of nerve-influence, but rather of the view I am aiming at developing in this paper—that in a gland secretion is only a manifestation of the healthy life of its cells, an *essential* part of their nutritive history. When the nerves of a gland, after section, are not regenerated, such gland undergoes degenerative changes (Heidenhain). As is well known, the changes in the cells of the digestive glands dependent on nerve-stimulation can be observed microscopically, even in the living gland. As to whether there are separate[5] nerve-fibres concerned in the various processes which constitute the cycle of changes in gland-cells is, for my present purpose, a minor consideration. That there should be division of labor in nerve-fibres, as elsewhere, seems *a priori* probable. But it is important to have it clearly understood that the changes effected are directly dependent on nerves, and not necessarily on blood-pressure or the blood itself. The well-known fact that there may be secretion of saliva in a decapitated animal, on appropriate nerve-stimulation; and that on stimulation of the sciatic nerve in an animal already dead, as I have myself demonstrated in the cat, there may be sweating of the corresponding foot, shows clearly that while the blood supplies the crude pabulum, the real life of the tissue is absolutely dependent on nerve-influence; and be it noted that unless this *functional* life is maintained the tissue, as a tissue, whatever it be, gland, muscle, or what not, degenerates. Not to multiply instances, I think it will now be clear that the ground I have taken as to the constant outflow of nerve-influences on all the tissues being essential to their welfare and functional integrity is well supported by different kinds of facts. The reason that functional activity is bound up so closely with the *highest* welfare of a tissue is, that more of the vitalizing nerve-influence is called forth under such circumstances. I wish especially to insist that the functional activity of an organ is in reality but little more than an exaggeration of its resting state. This is shown by the chemical products of muscular metabolism being only increased, not different, whether the muscle be at rest or in action.

I do not forget that there are groups of animals in which no nervous elements of any kind have yet been recognized; but, in the first place, the nerve-horizon, like the palæontological, is being pushed lower and lower by our improved methods and instruments; and, again, such organisms are of the simplest kind, and their co-ordinations are few and uncomplicated. In mammals, and especially in man, the nervous system is the sovereign—a somewhat considerate one, however, ready to listen to the slightest prompting from any tissue however humble, but one whose subjects have so long been dependent on him that now they are absolutely unable to take care of themselves, or even subsist without him, however abundant the nutritive pabulum may be.

Granting this position to be sound, it is not difficult to understand why sexual excesses, with their enormous drain upon the nerve-forces, should leave a residue inadequate to meet the demands of the various tissues and organs. The heart is constantly in need of nerve-support; and when that is not forthcoming, the various evidences of imperfect nutrition manifest themselves, such as irregularity, dilatation, etc. The cause of the "irritable" heart is thus patent. The sudden and marked alterations in blood-pressure, in the rate of the heart-beat, and other disturbances owing to nervous overflow, effects manifest, *e. g.*, in the respiratory system, through its own centre—are all causes, or rather occasions for the cardiac disturbance; but, as I view the condition of things, quite subordinate to the general loss of nerve-force—the emptying of the reservoirs of life, as this view will warrant denominating the nerve centres.

Testing the question of athletic strain from this standpoint, we proceed to ascertain how the facts harmonize with the theory. It is notorious that some men cannot successfully undergo training at all from the athletic point of view. They every now and then break down somewhere, if not generally; they "go off training," as the expression is. The meaning of this is, simply, that the organization of these men is such that it cannot bear the nutritive strain demanded by the excessive muscular exercise; and if nutritive capacity is dependent largely on the supply of central nerve-force, it is easy to understand the condition. The break-down of athletes is often in the digestive organs. Force has been unduly diverted to the muscles, and insufficient is left for the other tissues. Consider what happens with an average college racing crew. Such men are supposed to do some study for at least a portion of the year; they do not understand their capabilities like old professionals; and, above all, the circumstances in which they are placed, with the eyes of a whole college, and, as they feel, perhaps, of an entire country upon them, they are the subjects of nervous exhaustion, owing to undue emotional excitement, for weeks before the contest. Often they sleep badly for days prior to the final event, and enter the boat conscious that they are not at their best. But they are determined to win or die; and with corresponding results in not a few cases.

I am persuaded that we are justified in assuming the existence of what I shall denominate *residual nerve-force*. On this, Nature does not usually call, even when a man

[5] Journal of Physiology, vol. vi.

makes powerful efforts; but under extraordinary excitement, even this last resource is drawn upon, and invariably with the result of leaving the organism more or less bankrupted.[1] Such happens often, I believe, in the boat-races of amateurs. One of the most famous oarsmen in the world informed me that for two or three days before a race he exercised very little, slept more than usual, and in various respects allowed his organism to have its own way, so to speak. Being of an equable mind and a model physically, with especially fine circulatory organs, he never seriously broke down. He economized his forces, which gathered head before the excessive demand was made upon them. One thing is certain, a man cannot use his mind actively and be an athlete at the same time; which is plain enough, according to the views I am maintaining, but is not explicable, so far as I can see, on any other grounds.[2]

Physiologists, as a class, have paid little attention to comparison of results obtained from the study of different groups of animals (the morphologists have been wiser in their generation); while individual differences have, too generally, either been ignored or eliminated as the evidences of unsuccessful or undesirable experiments. In gaining accuracy, they have lost in breadth and depth of vision. Being convinced of the dangers surrounding, if not necessarily incident to, such a course, the comparative method has pervaded all that I have myself worked out in cardiac physiology. H. C. Wood,[3] also, has pointed out that in certain races of hunting dogs and in wild rabbits the vagi are capable of exercising unusual control over the heart, etc. He infers that a similar difference may exist in successful athletes. My own papers abound in recognitions of individual differences of every kind. Physiology must recognize such, if ever it is to explain facts fully for the physician.

There are some remarkable facts in connection with heart disease which have never been adequately explained, but which seem to follow almost as corollaries from my theory. Let us examine hypertrophy and dilatation in the light of these explanations. Hypertrophy occurs when the heart does increased work—when the intra-cardiac pressure is augmented. The obstruction leading to this is not the real or efficient cause of the hypertrophy; nor is the increased flow of blood to the muscular tissue, during and after contraction, the real cause, any more than increased feeding is the cause of unusual growth in an organism as a whole. The growth depends on the assimilative capacity which resides in the tissue itself, and which is dependent on the vitalizing nerve-force (neuro-trophic influence) sent to it from some centre. How is it that there is failure of compensation in hypertrophy? How is it that such failure is sudden in some persons? How is it that under circumstances when the mechanical strain on the heart is approximately equally great for each person (racing crew), only one may suffer from any form of cardiac failure? How is it that dilatation may occur suddenly from some emotional strain, and be recovered from? These and many other apparent puzzles become clear enough if we suppose that the neuro-trophic influence, necessary for the maintenance of every tissue in health, is not forthcoming. I wish especially to insist that in this respect the heart is not exceptional. It falls under one broad law which applies to the whole vital economy. There are, of course, cases in which the failure—be it local softening, myo-carditis, or one of various other lesions—is clearly owing to deficient pabulum, the blood not passing freely into the coronary arteries. Such cases find a ready explanation.

It is pleasing to notice that we are beginning to realize that there may be serious disease apart from any changes in a tissue recognizable by the microscope. Medicine is emerging from the dominancy of anatomy, with its grosser conceptions. Niemeyer,[1] quoted by Osler,[2] who assents to his view, held "that it is not possible by means of the microscope to recognize all the alterations of the muscular fibrillæ which diminish the functional power of the heart." I have myself elsewhere[3] drawn attention to serious physical changes having been experimentally *demonstrated* in arteries, with at the same time no changes of their coats, even microscopically recognizable and have suggested some important questions for consideration. If we but once thoroughly realize that the most pronounced functional changes of an organ are not necessarily connected with other than molecular changes, I am convinced we shall be in harmony with the best teachings of science, and be prepared for advances both scientific and practical. A good deal of interest has been manifested in mimic aneurisms, so-called. Osler[4] has very recently directed attention to a case in which there was dilatation of large arteries with no visible lesions. This also finds its explanation under the neuro-trophic theory which I advance. Such dilatations may be temporary (mimic aneurisms); they usually occur in nervous persons; and they are probably due to molecular changes in the vessel-wall, under the influence of the nervous system, in some way not yet clear as to details. That some molecular change takes place in the nervous centres themselves as a consequence of sexual excesses is evident, when we consider the impairment of mental power, and especially of memory, that follows, and which is gradually recovered from in favorable cases after a complete correction of the habits. The fact that the changes are molecular at first in many, if not all diseases, has encouraging aspects to it. What the nervous system has done under worry, etc., it may undo. I would point out, by the way, that the Weir-Mitchell method of treatment *practically* recognizes the neuro-trophic theory; were it not so, the feeding part might do more harm than good. If my views are correct, it is possible to make exercise a remedy for cardiac and other diseases—in fact, such follows as a natural sequence to the theory. But, above all, the question must often be, "Canst thou minister to a mind diseased?" The very fact that such ministration has been successful is also in itself an additional confirmation of what is now advanced. Flint[5] has well pointed out that in recruits there is often much mental disturbance; otherwise the merely mechanical strain on the heart would probably be, in many a case, quite insufficient to induce the "irritable heart."

It is a singular fact that in some maladies of the heart the left ventricle is more affected than the right. There are reasons for this beyond those that appear upon the surface, such as increased mechanical strain of this ventricle, which is, of course, from my point of view, only the occasion, not the real cause, which is increased nutritive strain. I submit some other facts for consideration. In the evolution of the heart in the animal scale we have a series of graded complexity: First, a simple pulsating tube, as in worms, gradually getting more complex, till, in the lower vertebrates (fishes), we have the *sinus venosus* and the single auricle and ventricle; in one group of fishes (dipnoi) a second less perfect auricle is found; in the batrachians two auricles, both well developed; in

---

The effort that sacrifices the constitution may be a mental one. The following incident will illustrate this: A clergyman, when crossing the Atlantic, a disaster having overtaken the ship on which he was a passenger, found himself suddenly in the midst of panic-stricken fellow-travellers and crew. The officers had lost all control. This man by superhuman efforts restored order; but the task bankrupted his vital (nervous) forces, and he was never afterwards capable of anything in which serious responsibility was involved. I relate this incident on the authority of a well-known clergyman of the same denomination as the unfortunate hero himself. In a minor degree I think we may see the principle often illustrated. For example, it throws much light on the evils of competitive examinations.

[2] I speak, in the matter of athletism, both from observation and experience. Some years since I did a good deal of hard rowing, though I never felt warranted in entering upon competitive trials. The only occasion on which I noticed marked irregularity of my own heart was on rowing in the evening of a day spent in close mental application. This experience conveyed a practical lesson to me upon which I have acted ever since.

the turtle-tribe a partially divided single ventricle; while it is not till the alligator is reached that we have the five chambers separate and complete. After watching the hearts of the various cold-blooded animals I have studied, through all their different phases of nutrition, I was able to determine the relative vitality of each part of the heart, and to reduce the results to the form of a general law,[1] viz.: That the part of the heart soonest to die, the conditions of nutrition being equal, is the ventricle—and of this the right moiety, when the chamber is not completely divided off; or, if there be two ventricles, the right has the greatest vitality. Invariably the *sinus venosus* is the last to pulsate. The hearts of the higher mammals also conform to this law. I have seen the great veins at their junction with the heart (representing in part the *sinus venosus*) pulsating, in a rabbit, long after the whole of the rest of the heart had ceased to beat. The reason of the greater vitality in mammals of the parts indicated is clear only on the principles of evolution. It is scarcely a metaphor to say that man carries in his bosom something of the fish, tortoise, snake, etc., and well for him he does, otherwise his years would probably be fewer than threescore-and-ten. The left ventricle is a late and special development to meet the needs of an exceedingly complex organization. It must be highly sensitive, to respond to the countless adjustments required of it; but that very sensitiveness exposes it to disease.

It is not possible to understand in a broad sense the relations of cardiac diseases in man, without bearing in mind the enormous and disproportionate development of his cerebral lobes. The cerebrum is constantly interfering with the action of lower centres and modifying the whole life of the animal. Witness reflex fainting by vagus-inhibition effected through afferent nerves from the eye, the ear, etc. (appalling sights, evil tidings); but the countless inhibitions or other interferences, less striking, pass unnoticed by us, though not unfelt in the heart's nutrition. Man is essentially a worrying animal; fortunately he is also the most susceptible to emotions that are replete with health-restoring energy, which can be readily understood in the light of my neuro-trophic theory. In this connection the cases recently alluded to by Broadbent[2] in his Croonian lectures are most suggestive, and are confirmative of these views.

I wish to bring to the notice of philosophic physicians certain observations and experiments which deserve to be better known. Kronecker has drawn attention to a certain peculiar and (in the dog) fatal behavior of the heart, which consists in an unco-ordinated fibrillar action of the ventricles, wholly beyond vagus-control. It may be induced by needle-puncture, electricity (and when the heart is much exhausted, even by manipulation), applied to a certain region (regions?) of the heart. Kronecker thought it due to injury of a hypothetical co-ordinating centre; but from my own study of the hearts of the cold-blooded animals, as well as from what I have seen of it in the dog, I am inclined to attribute the phenomenon to the independent action of the muscular fibres themselves when their nutrition is bad; or, at all events, not through any action of ganglion-cells, though possibly the nerves of the cardiac substance may be concerned. Some stimulus is, of course, required—often but a slight one, to induce the result. Kronecker thought this behavior of the heart explained why very slight wounds of this organ sometimes proved fatal; while at other times larger ones seemed of little consequence.[3] I would suggest that this peculiar action of the heart in lower mammals, etc., throws much light on the behavior of the heart of man in certain ill-understood conditions, as in angina, especially when fatal, and, perhaps, in thrombosis of the coronary arteries; indeed, in any condition in which there is defective nutrition of a well-pronounced character. I have elsewhere[1] called attention to certain experiments on ligating the coronary artery which deserve special mention in connection with the pathology of those affections referred to above. Flint[2] and others have argued well for ischæmia as a cause of angina; and the experiments just referred to, as well as Kronecker's and my own, lend strong additional support to such a view. I would, however, substitute *mal nutrition*, of which ischæmia may itself be the chief cause, as a conception of the cardiac condition more in harmony with the most recent physiological views. The nervous element must not be left out, for certain attacks of angina (as in Hunter's case) are directly traceable to emotion. The possible effects of vasomotor nerves must also be taken into the account, and largely, too.

Before passing on to the second part of this paper, I may remark that there are many points either referred to or developed in the recent lectures of Macalister, and also of Warner,[3] on allied subjects, which tend to strengthen the theory of nutrition I am maintaining in this paper, but to which the limits of space will not permit me to refer.

II.

It now remains to indicate: (1) Which nerves constitute the channels by which nervous forces reach the heart and affect that organ; (2) what the manifestations of such influence really are. It is especially on this part of the subject that my own and others' researches on the cardiac nerves have thrown a new light. It will be necessary, however, to deal with this portion of the work much more briefly than, perhaps, might be desirable. But those who are inclined to look more carefully into the matter will probably be willing to consult the original papers.[4]

The depressing action of the vagus-nerve was that chiefly regarded by physiologists, till very lately. As will be seen, this depressing action is but a part of the whole, and the less important part by far. After the most careful examination of the action of the pneumogastric nerve on the heart in the water-tortoise[5] (Slider Terrapin), under every conceivable condition of cardiac nutrition, I was led to conclude that this nerve was essentially bound up with the best welfare—the highest nutritive interests—of the heart. I found, further, that a comparison of hundreds of experiments justified the law I then laid down, viz.: *That the beneficent action of the vagus was in direct proportion to the needs of the organ at the time.* When I discovered this connection, which all my own subsequent investigations, as well as those of others, have only tended to strengthen, I felt that there must be a world of physiological meaning in it, and a significance of the highest moment for medicine. Instead of dwelling on multitudinous details, I shall refer to a single experiment which speaks volumes in itself. In a tortoise that had been the subject of experiment during two successive days, the sinus and auricles were beating but slowly and feebly; the *ventricle, with the exception of a few fibres, had ceased.* After a series of stimulations of the vagus, the rhythm was more than doubled, and the ventricle, which at first responded only to every two or three beats of the auricles, *then pulsated after each beat* of the auricles. It will be noted that similar though less marked good effects have been witnessed as a result of vagus-stimulation in all the animals examined by me; and I have seen no exception to this,

[4] My own researches on the cardiac physiology of the Sea-Turtle (first paper, the Slider Terrapin, the Fish, and Menobranchus, have appeared in the Journal of Physiology, vols. v., vi., vii., and on the alligator, the Sea-Turtle (longer paper), in the Journal of Anatomy and Physiology, vols. xx., xxi. My paper on the heart of the snake is to appear in the October number of the Journal of Anat. and Phys. for the current year.
Most of the papers by others on the innervation of the heart will be found in the Journal of Phys. A paper on the heart of the frog by the German physiologist Heidenhain appeared in Pflüger's Archiv, bd. xxvii.
[5] Journal of Phys., vol. vi.

though I must have stimulated the vagus thousands of times during the past three years. But the sympathetic accelerator fibres and the sympathetic main stem have appeared in a new light also. The sympathetic cardiac accelerators have now been pretty thoroughly worked out both anatomically and physiologically, by others and myself, for several cold blooded animals.[1] When working on this subject in the terrapin certain remarkable, puzzling, and hitherto unobserved effects were noticed. Thus, not only did stimulation of the part of the main sympathetic cord (in which the accelerator fibres run upward to the ganglia, from which they finally proceed as isolated branches to the heart) produce augmentation of the force and acceleration of the rate of the beat; but as I pointed out, for the first time, this primary effect was followed by slowing and irregularity of the heart. It was thus seen that the vagus and sympathetic had a physiological resemblance; and what I wrote then, "The vagus is a sympathetic with inhibitory fibres, the sympathetic a vagus without them," has proved true. I had noticed[2] that the immediate effects of stimulating that portion of the main sympathetic stem in which the cardiac accelerating fibres run had, in one instance, produced effects as remarkable as those cited above for the vagus. It was observed that both nerves had the power of augmenting the heart's activity; with the vagus it was an after-effect, with the sympathetic a primary one. In the case of the vagus the slowing, irregularity, or arrest is primary; with the sympathetic it is secondary. The nerves were thus seen to be physiologically similar, and yet different. Gaskell,[3] by stimulation of the sympathetic fibres, which run in the vagus trunk, while still separate within the cranium, in the frog, got purely depressing effects; and I found irregularity and other evidence of a depressing influence on similar intra-cranial stimulation in the terrapin.[4] The evidence was thus accumulating to give a substantial basis to Ransom's[5] conception that there might prove to be in the vagus true inhibitory fibres which tend to increase *constructive* cardiac metabolism, and sympathetic fibres which favor *destructive* metabolism. Gaskell[6] has, in a more recent paper, further elaborated this theory; so that now we may feel warranted in regarding the vagus as being demonstrably a vago-sympathetic nerve. It therefore follows that those influences of a nutritive character which reach the heart pass by three different avenues: (1) As conservers, constructors of cell-tissue, by the vagus in its inhibitory fibres proper. (2) With the reverse action, by sympathetic fibres in the vagus itself and in the main sympathetic stem, finally to emerge as accelerator (augmentor) nerves. When the vago-sympathetic nerve is stimulated, the inhibitory fibres have apparently the predominant effect; that they continue to do so to the very end of the chapter I am, however, by no means certain. It is true, these conclusions are founded chiefly on the study of cold-blooded animals; but it is likely that so general a law holds in the main for mammals, including man. In making the applications to pathology it may, first of all, be remarked that it is within every observer's experience that events may take place in the cerebrum which inhibit or otherwise influence lower centres. Witness the cessation of labor-pains on the entrance of the accoucheur; the behavior of the sexual centre; the inhibition of the defecating centre by mental preoccupation at the usual period of its action.

Hewan,[7] reporting his own case, states that after intense study his heart-beat fell from 72 to 28 in the minute. It is possible to interpret this result either by the increased action of the inhibitory fibres or deficient influence from the sympathetic fibres. At all events, there was cardiac disturbance, plainly traceable to the nerve-centres.

What is the mechanism of cardiac acceleration? Usually Marey's law holds that "the rate of the beat is in inverse ratio to the arterial pressure." In disease, however, the heart has often to choose between two alternatives, either to contract against undue resistance or not to contract at all. Normally, as Sewall[1] has shown, the depressor nerve (rabbit) acts as a reporter to the cardio-inhibitory centre, indicating the degree of intra-cardiac blood-pressure, and thus the heart in health conforms to Marey's law. In a case of dilatation, following, say, an athletic contest, it is possible to understand that the destructive metabolism, brought about by the accelerating sympathetic fibres, was so far in excess of the constructive effected through the vagus inhibitory fibres, that molecular changes take place which are the real cause of the dilatation. The latter, as I view it, implies essentially molecular changes in the cardiac tissue. We must not conceive of the heart as of so much leather stretching under obstruction. When a skeletal muscle acts against a certain opposing force it does more work; but when that force is increased beyond a limited point the muscular elasticity is lost for a time. This can be shown experimentally on excised muscles. The loss of elasticity indicates molecular changes; but the case of the heart is not precisely parallel with that of an excised muscle. It has the choice of being stretched or not, so to speak, and it does not elect the former *so long as the balance of nerve-force is maintained*. This balance is preserved or lost according as the influences which reach it through the inhibitory fibres of the vagus exceed or fall short of those by the sympathetic.

The present state of cardiac physiology enables us the better to understand such forms of disease as Basedow's; how, for example, the mental state can influence the heart for good or ill. Many German writers,[2] Bartholow[3] and others, have stated that galvanization of the nerves (sympathetic) has proved valuable in the treatment of Basedow's disease. It is well known that the conductivity and irritability of a nerve may be lowered by the passage of a constant current through it. As this effect is temporary, we may suppose it due to some molecular change; but from this result we can understand the good that follows the use of electricity, whether the undue irritability in this and other diseases be referred to the muscle, the nerve, or the discharging centre.

Perhaps the time is not yet ripe for us to determine in a special case whether the vagus-fibres proper or the sympathetic fibres are at fault; but it must be clear that we now know enough to enable us to adopt theories less mechanical, more fundamental, and more in harmony with the ascertained facts, not only of medicine but of other sciences. In connection with these considerations, what has been insisted upon in the earlier part of the paper must not be forgotten. After all, the condition of the nervous *centre* is the main thing in most cases. It is not to be forgotten that nerves are but conductors, which may, however, be diseased. I think I can myself foresee how such views as I have endeavored to present in this paper must lead to a wiser prognosis and a more rational treatment.

It seems desirable that we should endeavor to form some definite conception of why and how the heart happens to beat at all. This problem I attempted to solve, as best the evidence we now have would allow, in a paper[4] published a few months since; and I present here for consideration the summarized conclusions of that study.

1. The factors entering into the causation of the heart-beat of all vertebrates as yet examined are: (*a*) a

tendency to spontaneous contraction of the muscle cells composing the heart; (*b*) intra-cardiac pressure; (*c*) condition of nutrition as determined directly by the blood, and indirectly by the nervous supply of the organ.

2. The tendency to spontaneous contraction of muscle cells is most marked in the oldest parts of the heart ancestrally considered. I have shown (*Jour. of Anat. and Phys.*, Vol. XXI) that in the Sea-turtle the last segments of the ventricle to pulsate are on its extreme right; while the right auricle outlasts the left, and the sinus and great veins beat much longer still. The same has been noticed in several other groups of animals. The most recently acquired parts of the heart always are the first to lose functional activity. These are but extensions of Harvey's observations, seen in the light of evolution.

3. In all hearts examined, intra-cardiac pressure is a factor of considerable importance; in some, as that of the Fish, Menobranchus, etc., it is apparently the controlling factor. The same may be said of the molluscan heart.

4. The power one contracting cell when in action seems to possess of initiating a similar state in others, is of great significance.

5. The influence of the nerves of the heart appear more and more as we ascend the animal scale. They seem only indirectly concerned in the causation of the beat by their influence over nutritive processes; but as the heart is being so frequently modified in its action, their influence in highly developed hearts becomes an almost constant factor, and of a degree of importance which our knowledge of the relation of nerve to muscle enables us but inadequately to appreciate, but which the pathological changes ensuing on nerve section illustrate.

6. It almost follows from the above that one part of the heart having contracted the other parts must follow. This is probably the explanation of the rapid onset of the ventricular after the auricular systole in the mammal. It will be remembered, too, that even in the mammal contraction begins in the great veins entering the heart.

The basis of all these explanations is found, in reality, in the *natural contractility of protoplasm*. A heart in its most developed condition still retains, so to speak, the inherited but modified Amœba in its every cell.

JAUNDICE IN TYPHOID FEVER.

BY HARRY D. HILL, M.D.,

ADRIAN, MICH.

The variety of this complication has induced me to give the following history, and the paucity of its literature is my excuse for the apparently unnecessary minuteness of detail.

Mr. Geo. W——, aged sixty-four, came under the care of Dr. J. Tripp of this city, August 31st. Was of billious temperament, with a history of jaundice when a young man, and of repeated "billious attacks" since. Was taken sick Sunday, August 28th. Had a chill, epigastric pain and vomiting, but treated himself with home remedies until Wednesday, August 31st, when Dr. Tripp was called. At this time the pulse was 90, temperature 101.

The disease advanced through the regular stages of typhoid (the evening temperature at no time being higher than 102 1-2) until September 10th, when the fever gradually subsided, and by September 14th a sub-normal temperature was reached and convalescence apparently established. On the evening of September 19th, after taking a small drink of lemonade, the patient was attacked by vomiting; this lasted a short time, but was followed by a rise in temperature and pulse. The temperature and pulse gradually became higher from that time until September 24th, when it reached its highest point 102 3-4. The pulse, 80 on September 19th, had gradually risen to 120.

The vomiting, which began the evening of the 19th, was followed by nausea and several slight attacks of vomiting, which culminated in a free emesis of bile—a half teacup full—on the evening of the 20th.

During the entire sickness there had been absent any abdominal symptoms that were serious. At no time had there been any tympanitis or tenderness to any extent.

The bowels had moved twice a day with a gradual increasing consistency, and return to normal color.

The urine had been very plenty, and during the last five days before death over-abundant. Bile was first noticed in the urine September 23d (the day before death).

The face was slightly colored the 22d, but not enough to excite suspicion.

On the afternoon of September 23d, I was called in consultation with Dr. Tripp, and found the patient with a face slightly jaundiced, skin elsewhere not discolored.

The urine abundant, albuminous and filled with bile. Pulse 130, temperature 101¾, respiration 30.

The heart's action, though rapid, was regular, and no weaker than would have been expected after a fever of three weeks' duration. Both sounds distinct, and no murmurs.

Abdomen not tender or tympanitic. Hepatic dullness somewhat lessened, and spleen enlarged. Tongue moist and slightly coated. Senses normal. Skin cool. No apparent disturbance of the nervous system.

By 7 A.M. the next day (September 24th) a startling change had taken place.

The face was a deep yellow, conjunctiva and sclerotic discolored, and entire body a light yellow. Abdomen not tympanitic, but tender on percussion over liver at lower border. Had had no passages for the past twenty-four hours, contrary to previous habit. Liver and spleen the same as before. Temperature 102¾, pulse 140, respiration 35. Pulse intermittent; at this time the sounds of the heart could not be distinguished from each other. Mild delirium and subsultus tendinum.

10 A.M., respiration 40, temperature 101¾, pulse 148.

2 P.M., respiration 48, temperature 101, pulse 154.

5 P.M., respiration 52, temperature 100, pulse 150.

At 8 P. M., the heart's action seemed stronger and the sounds could be readily distinguished for the first time during the day.

Resp. 40, temp. 100, pulse, 135.

At 10 P. M., respiration became impeded, ran up to 68–72, and death took place from pulmonary obstruction at 1.30 A.M., the heart's action remaining almost unchanged until midnight. No post-mortem was allowed.

The symptoms of hepatogenic jaundice, as observed in this case, seems to differ materially from those in cases on record, and are contrary to some almost accepted facts in regard to bile absorption.

Landois says, "the heart beats are generally diminished, *e. g.*, to 40 a minute. This is due to the action of the bile salts, which at first stimulate the cardiac ganglia, and then weaken them. There is slowing of respiration and diminution of temperature.

Lowitt, after injecting bile into animals, "observed phenomena, referable to stimulation of the respiratory cardio-inhibitory and vasa-motor nerve centres."

Leyden noticed an increase of 15–24 beats to the quarter after injection of bile.

Legg says, "In my own experiments on the frog I invariably noticed a slight rise from 9–11 beats in the quarter minute, and these experiments were made without disturbing the heart, by the injection of bile acid solutions under the skin."

Traube says, "If this system (regulating system) be active there is seen after injections of the bile acids a lowering of the blood pressure, with a considerable rise in the number of the pulse.

Flint, Sr., says, as follows: "Bile in the blood acts as a sedative on the circulation and nervous system. The heart's action is usually diminished in frequency. Pulse frequently falls to 50–40 or even lower in cases in which the jaundice is not associated with fever; and if thus associated, the frequency of the pulse is lower than if jaundice did not exist.

Numerous other authorities seem to agree on the fact that absorption of the bile retards the circulation and lowers the temperature. It is however certain that such was not the fact in this case. Possibly the blood pressure lowered by the paralyzing effect of the poison on the vasa-motor system, causing an increase in the pulse rate.

The literature on this subject is very scanty.

Immerman gives a history of one case of hematogenous jaundice following a moderately severe case of typhoid, treated by quinine. The first appearance of the jaundice was noticed in the fifth week. In this case, although the urine was black no bile pigment was found, the bile passing off with the stools. A post-mortem revealed a liver in the early stages of cirrhosis.

French gives two cases; in one the jaundice began the second day after admission to the hospital. Death took place in eight days. In this case the temperature and pulse were both lowered, a beginning fatty degeneration of the liver was found at the post-mortem.

In the second case, the jaundice was noticed after a severe chill on the twenty-first day of the fever. No record of temperature or pulse. Death occurred on the third day from pulmonary œdema. An autopsy found softened spots in the liver with absence of normally formed granular cells.

Murchison gives nine cases, all of which were fatal except one.

Griesinger reports ten out of six hundred cases of typhoid.

Hoffman reports 250 fatal cases of typhoid, in 10 of which jaundice occurred. In the majority of these cases jaundice was not seen till late in the disease.

Fischermeister met with it six times in 1420 cases.

Zenner and Legg never saw the complication.

Jas. H. Hutchinson says: "I have never seen this complication, and am inclined to think it rare in this country."

Wood, although giving no report of any case, says: "There is another class of cases more rapid and violent, in which the prominent symptoms are those of gastric or hepatic disorder. Along with the characteristic symptoms of enteric fever we have much nausea and vomiting often of bilious matter, and not unfrequently yellowishness of skin. They are apt to run their course rapidly, and sometimes terminate fatally before the rose colored eruption has appeared."

The noticeable features of the present case are:

1. The insidiousness of the attack, the pulse respiration and temperature gradually rising for five days without apparent cause.

2. The action of the absorbed bile, apparently contrary to that met with by other observers. the pulse and respiration in this case being increased to the end.

3. The prompt interference with respiration when nervous symptoms intervened, and the rapid lowering of the temperature.

4. The rapid progress to a fatal issue.

5. The lack of apparent cause for the complication, the fever having been extremely mild throughout.

It has occurred to me that the latter symptoms in this case bear a striking resemblance to those of acute yellow atrophy, and it is not only possible but also probable that the pathological conditions are similar. In addition to the changes in the liver structure, the albumen in the urine—in this case—would suggest degeneration of the kidneys.

Treatment offers no encouragement.

If, as the writer believes, the jaundice is only the external manifestation of the extent of the internal destruction, treatment seems futile.

Nourishment, stimulants and possibly the mineral acids are the remedies from which we would naturally expect the best results possible under such circumstances.

The gravity of the complications, however, cannot be over-estimated.

SUBMUCOUS INJECTIONS IN CHRONIC THROAT AND NASAL DISEASES.

By W. F. CHAPPELL, M.D.,

NEW YORK.

So much has been written on the methods of treating these diseases, that, were it not for the frequent negative results obtained in a large percentage of cases, I would hesitate to add to the already long list of methods and remedies.

In submucous injections I believe we have a very important means of aiding recovery, especially in Naso-pharyngeal Catarrh, and Follicular Pharyngitis.

A curved pointed needle is used for the throat, and will fit most hypodermic syringes. At each sitting I select three or four of the largest groups or tries of vessels seen in the mucous membrane, chiefly on the posterior wall of the pharynx, and the anterior pillars of the fauces and uvula, and introduce the needle into the main trunk of each cluster, and inject one drop of a solution of equal parts of carbolic acid and glycerine. A whitish appearance is immediately noticed at point of injection; in three or four days the entire cluster will be less distinct, and eventually disappear. This method diminishes the vascular supply, secretion, and hypertrophied condition of the mucous membrane, and leaves it in a paler and more natural condition.

In follicular pharyngitis each hypertrophied follicle is hooked up with the needle, and one drop of the carbolic solution injected. This is followed by a reduction of the hypertrophic conditions without any cicatrix or perceptible change in the membrane. In making the injection, some practice is necessary to lodge the drop in the membrane without its escaping where the needle is withdrawn. To effect this. the puncture must be from above, downwards. Cocaine is rarely necessary.

The straight needle is for submucous injection of nasal hypertrophies, and has given me more effectual and permanent results than other methods.

I have experimented with several acids, but up to the present have had the best results from monochlorecetic, saturated solutions.

After spraying the part with Dobell's solution, I apply cotton saturated with an eight per cent. solution of cocaine, and allow it to remain about six minutes. I then charge the syringe, dip the needle in vaseline, and introduce it beneath the mucous membrane, on the free surface of the hypertrophic, and inject one or two drops of the acid, then withdraw the needle and cleanse syringe in an alkaline solution.

The injection is followed in most cases by some pain and hemorrhage of short duration.

Fourteen to twenty-one days is the time required to complete the change in the hypertrophic; a second injection is rarely necessary, excepting in very large growths.

The needle must not be introduced at the base of the hypertrophic nor deep into its substance, or it may result in an unnecessary loss of tissue and œdema of the face, which, however, soon disappears. Care should also be taken that the opening in the point of the needle is beneath the membrane, otherwise the acid may be lodged in the throat.

I find that some cases of elongated uvula will atrophy when injected with carbolic acid.

22 EAST 42ND STREET

PERIODICALLY RECURRING OCULO-MOTOR PARALYSIS,—A DESCRIPTION OF A PAROXYSM, WITH AN ATTEMPT AT LOCALIZATION, AND WITH SUGGESTIONS AS TO THE PATHOLOGY OF THE DISEASE.

By ALFRED HINDE, M.D.,

SURGEON TO THE EYE AND EAR CLINIC CENTRAL DISPENSARY; INSTRUCTOR IN EYE AND EAR DISEASES, POST-GRADUATE MEDICAL SCHOOL; OPHTHALMOLOGIST TO THE NEURALOGICAL CLINIC OF RUSH MEDICAL COLLEGE, CHICAGO, ILL.

As a preamble to this supplementary description of a paroxysm in the patient, T. S.———, referred to in other papers on "Periodically Recurring Oculo-motor Paralysis," read before the Chicago Medical Society, June 20th, 1887, and published in the N. Y. Medical Record Sept. 24th, 1887, we may state that the case was irregularly under observation during a period of six to eight weeks, during which time she was taking a mixture of the Iodide of Potassium and Bichloride of Mercury. Whether this had any influence on the ptosis of the left upper eyelid is questionable, yet the power of the levator palpebræ superioris returned sufficiently to permit a palpebral fissure, on voluntary effort,—of about 3‴ at its widest part. No gain was apparent in the other third nerve muscles in or out of the eyeball.

Nothing more was seen of the patient until the onset of this attack, and the present seizure is the first since March last.

August 8th.—9.30 A.M. Twenty-four hours ago menstruation commenced, and was accompanied by the usual slight pelvic pain, which lasts during the first twenty-four hours of each period. Last evening she retired in her usual health, and awoke during the night with a sensation of choking and with marked vertigo. This morning, about 4.30, she experienced a pain around the left eyeball, which almost immediately extended backward into the left half of the cerebrum, and did not involve the superficial tissues of the left side of the head. The pain rapidly increased in intensity, and was associated with nausea and vertigo, and about 7.30 A.M. she vomited. It is now, and has been from the commencement very severe, always present, of a sharp, shooting, stabbing character, and markedly paroxysmal. The paroxysms recur every three to five minutes, and last one to two minutes. Their approach is announced usually by the patient exclaiming: "The pain is coming again!" and immediately she commences to moan and toss around as if trying to find a place of rest. As the painful paroxysm eases off, so do the moaning and restless symptoms disappear, and in the intervals between the attacks she remains comparatively quiet. The nausea and vertigo, though continuously present, are very much aggravated during the paroxysms of pain, and in one of the latter she fainted completely away. The pulse was 78 and did not change in any particular during the pains. The temperature was $98\frac{2}{5}$.

The left palpebral fissure at its widest part measured about 3‴ when most open. The movements of the superior, inferior, and internal recti muscles were absent. The left pupil was dilated ad maximum, and was immobile. The eyeball was turned outward, and the movements of the external rectus were normal.

The tension of the left eyeball was natural, the fundus was normal apparently; the cornea was pressed upon with a pinhead, and the latter was scarcely felt. There was no injection of the conjunctiva, and no evidence of ocular inflammation. A freshly halved onion, and each half held equally near to the open eyes and with the same exposure, resulted in a marked reddening together with intense and lasting pain, and with profuse lachrymation of the left eye; whereas, in the right eye the only effect was a slight and transient smarting and no evident injection or lachrymation.

The sense of smell was found greatly impaired on the left side;—each nostril was tested separately, the left one first, and the fluids used were, oil of rose, assafoetida, and oil of mustard, and the odors were recognized only on the right side. Taste was tested with a saturated solution of Bromide of Potassium (for salt) dilute hydrochloric acid (for sour), and with tincture of Quassia (for bitter), and the left interior half of the tongue was first tested, and could not recognize the different tastes, whereas these were named when the right half of the tongue was touched with them. Hearing was tested and found to be alike and normal on both sides; she stated, however, that occasionally during the painful paroxysms she had transient tinnitus in the left ear only.

The cutaneous sense was also tested by stroking, pinching, pressing, pricking, and with a heated metal disk, and invariably the left upper quarter of the body, the left upper extremity to the finger tips, and the left half of the head and face were markedly anæsthetic. There was no cutaneous anæsthesia, however, present at this testing in the lower left trunk and the left inferior extremity.

To touch, the left half of the head and face felt hotter than the right, and it also looks somewhat redder.

The tongue was projected in the median line, and the grasp of the hands was strong and equal.

This observation extended over nearly one hour's time, and the changing phenomena did not vary in any particular.

At the patient's request she was sent to the Cook County Hospital, and was assigned to the service of Dr. D. G. Moore, and he courteously permitted me to continue my observations. I saw her at 3.20 P.M., and her condition was without change, save as follows: Her face looked blanched, and she appeared to be much depressed. Her pulse was 64, temperature $97\frac{3}{5}$° F., and she was vomiting frequently. The palpebral fissure was about 2‴ at its widest point. The paroxysms of pain were very frequent and severe, so that she scarcely had time to stop moaning, and rest between them.

At 6 P.M. the interne took her temperature with another thermometer, and found it to be $96\frac{6}{10}$° and the pulse 56.

9th.—3 P.M. Temperature $99\frac{1}{2}$°, pulse 56, and bounding. The paroxysms continued throughout the night, but with increasing intervals and decreasing severity, and kept up until 9 A.M. From that time until 3 P.M. there was no recurrence. During this observation, however, all at once she ejaculated: "The pain is coming again!" and so it did, and after moaning slightly and tossing momentarily, she was quiet once more—the pain was gone. This was the last paroxysm of pain, though a continuous pain in the head, sharp and stabbing in character, still remained. The special sense anæsthesia was unchanged, the left cornea was the same, but the cutaneous anæsthesia now involved the entire left half of the body, and ptosis of the left upper lid was complete. The vomiting stopped with the paroxysms. She said that the pain in the head was increased by raising the upper eye-lid of the left eye, and that she had noticed that, frequently toward the close of a painful paroxysm, tears flowed over the left cheek, but never from the right eye.

The latter observation we did not witness save in the onion test already mentioned.

10th.—3.45 P.M. Temperature $99\frac{3}{5}$°, pulse 52 and of fair tone. Pain in left half of cerebrum was still present but less severe. Left hemianæsthesia—special sense and skin was the same as before noted, and the left eye was also unchanged. No signs of hemiplegia were perceptible, heart and lungs were found to be normal.

11th.—1.45 P.M. Temperature $99\frac{1}{5}$, pulse 58 and good. She had some shooting pain in the left eyeball, which lasted about twelve hours, but otherwise there was no suffering—the continuous pain in the head having also ceased. The hemianæsthesia was the same as before noted. To-day for the first time appeared a marked difference in the grasp of the two hands, the left one being much the weaker of the two, and she said that in walking she noticed a weakness in the left lower extremity. The tongue was projected in the median line, yet she said

that there were times when she had great difficulty in formulating her thoughts and in expressing them—she "wants to talk but she cannot remember what to say," and her tongue seemed to be thick."

12th.—1.15 P. M. Temperature 98⅘, pulse 70. She was up and dressed, and said she felt much stronger though still very weak. Since admission to the hospital she slept none, and had only partaken of milk and iced-water. Her bowels moved daily, she said, and her menstruation had passed along without incident. Paræsthesia of the left half of the body have been present in the form of "numbness and wormlike crawling sensations in the skin." The cerebral-hemianæsthesia of the left half of the body was still as evident as ever, and the condition of the left eye was unchanged. The motor paresis of the left hand grasp was much less marked than on the 11th, and she walked stronger on the left leg. She considered herself well enough to leave the hospital, and asked to do so.

On the 15th she visited my office, and though her general strength was much improved the ptosis was still unchanged and the other third nerve muscles,—in and out of the eye—were completely paralysed. There was also an amaurotic condition of this left eye that no lens could improve, and she could not read any of the types. On ophthalmoscopic examination the two eyes were alike, and there was no perceptible disease of the left. On pressing the left eyeball backwards she complained of it hurting her, and said she felt a pain shoot clear back into her brain. The tension was still normal, and there was no injection of the ocular conjunctiva. The right eye was normal in every respect, and could read the finest type at the regular distance. The cutaneous hemianæsthesia and the special sense anæsthesia were still present on the left side, as was also the slight motor paresis, but the latter was even less worked than when last noted. On the following day she commenced her usual work as a laundress.

It had been her custom, in previous attacks to go to bed at once on their onset; but this time she did not do so, and to this she attributes the increased severity of the over previous seizures.

The case, however, appears to be following the usual course of the disease—viz., one of steadily increasing severity of attack and greater permanency of the sequelæ—and agrees fully with previous observations.

The pathology of recurrent oculo-motor paralysis is as yet an unknown quantity, for in the three recorded autopsies little can be learned, and no definite conclusion arrived at.

We may venture to account for the symptoms of our own case, and endeavor to localize the seat of lesion, but what may be the exact pathology cannot be definitely outlined, and our remarks may be considered as suggestive, and as an effort merely towards the solution of a comparatively new and interesting problem. The main features of the attack were its sudden onset, the great preponderance of sensory phenomena, the presence of angio-neurotic signs; and, lastly, the ptosis and the slight and transient hemiplegic symptoms, together with the amaurotic condition of the left eye.

The pain, so distinctly paroxysmal and so peculiarly neuralgic, lasted nearly thirty-six hours, and was among the earliest symptoms. So also was the anæsthesia of the left side, yet the cutaneous impairment did not affect the entire left half of the body until about the thirty-sixth hour of the attack. The ptosis became complete at that period also, but the hemiplegic symptoms were not observed until the fourth day of the disease; and the amaurosis appeared still later.

With the nausea, vomiting and occasional tinnitus aurium the entire phenomena of the attack were unquestionably central in origin, involving the sensory tract early and mainly; later the third nerve connections; and lastly, and to a very limited extent, the motor pathway.

In any attempt at localization the partially defined course of the sensory pathway must be considered, and in that portion of the latter above its junction with the fifth nerve (upper part of the pons) and its termination into the cortex is the situation where the pathological process in our case had its seat. Was it located in the pons and crus, in the internal capsule, or in the cerebral cortex?

We doubt that its course in the pons and crus was affected; possibly the pathway through the posterior third of the posterior limb of the internal capsule, the "sensory crossway"—was somewhat involved, yet instead of an hemianopsia of the same side (left), we found present an amaurosis,—a crossed amaurosis, we presume,—and probably a higher point is the more likely seat. Moreover, the sensory tract in the pons, crus and capsule occupies so circumscribed an area that disease so nearly limited to it, as shown in our case, and of so gradual an onset, is not easily imagined. Therefore, to the cortical terminations of the sensory pathway we look mainly for our pathology. Above the internal capsule the sensory tracts are divided up and scattered toward the "motor," parietal tempero-sphenoidal and occipital regions of the cerebral cortex; and mainly to the middle outer region of the cerebrum—that portion underlying the parietal bone. Gowns[1] writes "clinical evidence, as well as facts of anatomy, points to the outer part of the hemisphere in the middle region as being the part concerned in sensation," and he refers to the recorded case of Demange,[2] which "shows that the indication is correct, and places the conclusion" (as above given) "beyond doubt." This case, the main facts of which are almost the same as those of our own, came to autopsy, and the latter showed "an extensive area of cortical softening involving a large part of the outer surface of the right hemisphere and subjacent white substance; the inner surface of the hemisphere, central ganglia and internal capsule were unaffected," and he considers that "this case affords a crucial demonstration of the correctness of the indications afforded by the anatomical researches of Flechsig."

A lesion of the right cerebral cortex, commencing in the parietal portion,—clearing up the third nerve paralysis, the hemianæsthesia and special sense anæsthesia;—and with a steadily increasing area, spreading backwards to the occipital lobe,—explaining the amaurosis:—and reaching forwards to and including the anterior and posterior central convolutions and paracentral lobule,—thus interpreting the slight, transient and probably inhibitory hemiplegic symptoms; would seem to best explain the clinical facts of our case.

In the vascular supply of this extensive cortical region was the initial pathology, and the nervous element most probably affected was the ganglionic cell.

Of the arteries the middle cerebral is the most important, and especially the fourth branch of the same; for it supplies the convolutions around the posterior limb of the fissure of Sylvius–supramarginal, and angular and hinder part of the superior parietal and the first temporal.

The second and third branches mainly supply the greater portion of the "motor" cortex. The posterior cerebral supplies the occipital cortex. The paracentral lobule and the highest part of the ascending frontal convolution—part of the leg centre—are supplied by branches from the anterio-cerebral artery.

We can only guess at the pathology; "the picture looks like a very severe attack of hemicrania with paresis of sensation and motion thrown in to complete the background. A hemorrhage or embolism we cannot think of as a probable cause. An angio-neurosis is the possible key, associated with extra-vascular exudation and consequent compression of the surrounding nerve cells and fibres. From the early history of our patient the latter pathology would best account for the temporary motor-

[1] Lectures on Diseases of the Brain, 1885, p. 16.
[2] "Revue de Med." May, 1883, p. 391.

oculi paralysis. The earlier the history the less severe the seizure, and the more transient the results.

Of late years, however, the sequelæ have become more and more permanent, and we could imagine that what was in the early attacks merely an exudative pressure cause has latterly had the added factor of a localized degeneration.

The latter condition would seem to have impaired most markedly that portion of the third nerve's cortical connections from which spring the fibres supplying the recti and the intra-ocular muscles, but that portion of the centre from which the levator fibres spring is not as yet completely destroyed as shown by the partial restoration of function between the seizures. There would seem to be no anatomical change in the nerve structure of the motor area as yet, for the paresis is only transient and due to the enlarging zone of the pathological locality. Whether there is any permanent organic change in the sensory path can only be decided by further observation of the case, yet we suspect it on account of the constant condition of the hemianæsthesia—with the exception of the left lower quarter of the body.

The apparent hyperæsthesia of the secretory fibres of the left fifth nerve supplied to the conjunctiva and the lachrymal gland would seem to show fibres of separate and distinct function, together with irritation, or, more probably, diminution of cerebral inhibition of the same; whereas, the other sensory fibres of the fifth were subjected to paretic influences.

16 Laflin Street.

VARICOCELE. A SIMPLE OPERATION FOR ITS CURE.

BY HUBBARD W. MITCHELL, M.D.,

NEW YORK CITY.

The dilated and tortuous condition of the spermatic veins of the testicle, usually known as varicocele, is a disease that is met with not unfrequently. The dull, aching pain in the testicle and cord, and in the back, and the occasional melancholic symptoms it gives rise to, often render the sufferer incapable of attending to the active duties of life, and lead him sooner or later to seek advice of the surgeon. Horseback riding and outdoor labor aggravate this state of things, and present a complete bar to entrance into the military or naval service. Patients with varicocele suffer pain after coition, and hence often believe it leads eventually to impotence. Varicocele occurs more frequently upon the left side than upon the right owing to the anatomical disposition of the veins. The only effective *treatment* is a radical operation for the obliteration of the dilated veins.

A glance through the surgical text books, and medical journals written during the past twenty-five years, will show that a great number of operations have been advocated for the radical cure of varicocele. Many of them were ingenious, some positively barbarous, and every one capable of great improvement. It is now generally admitted that the best and safest method of radically curing varicocele, is by the *subcutaneous ligation* of the enlarged veins. To show how to do this in a very simple and easy way is the object of this paper.

During the past 15 months I have done this operation twelve times in private practice. The first six cases were done by the aid of a small needle, threaded with silk or catgut, or with a long needle and a silk loop. While the results were good, the method of operating was extremely unsatisfactory. The desire to simplify the operation and render it expeditious, and easy to perform, led me to devise a new varicocele needle, which is shown in the accompanying cut.

While there are other needles already in use similar to this, yet this possesses some new features, and decided advantages over any that have so far come under my notice.

It has a long and slender shaft, and a flattened oval-shaped point. The point, and sides, as far as the eye, are ground to an exceedingly fine sharp cutting edge. The eye is large and long, to readily allow the threading of the ligature. The handle is octagonal, and tapering, to permit a firm hold upon it, and flattened on the sides to correspond with the flattened side of the point, so that when the point is buried in the tissues, we can tell how to guide it.

By the aid of this little instrument, the operation for the subcutaneous ligation of the spermatic veins is extremely simple, and may briefly be described as follows:

The hair on the affected side of the scrotum may be shaved off front and back and the parts perfectly cleansed. A few minims of cocaine 4 per cent. sol. are injected under the skin at the seat of the operation.

The patient may stand up (if he is resolute enough), or, better still, lie down on a bed, sofa, or table. The operator now isolates the vas deferens, and holds it with his left hand to the inner side of the scrotum. With his right hand he takes the needle threaded with a sufficiently long silk ligature (previously boiled to make it antiseptic) the two ends of which he holds firmly with the handle. Holding the flattened point perpendicularly he plunges it quickly through the scrotum, the point with the ligature sticking out behind. He can now let go the vas deferens, and draw one end of the ligature out of the orifice of exit, and out of the eye of the needle. He now withdraws the needle, *back to, but not out of the orifice of entrance.* The point of the needle is now carried *subcutaneously* around the veins, and made to emerge *exactly* at the orifice of exit. Here the ligature is quickly and easily threaded into the *large eye*, and both withdrawn through the orifice of entrance. Carefully wash away any drops of blood that may ooze out, and tie a tight firm knot, which if properly done will completely occlude the veins. The ends of the ligature may be cut short, and the knot allowed to sink into the wound out of sight, where it remains permanently. A bit of adhesive plaster over the minute wounds completes the operation, and the patient may remain for a few days in bed. All this is done so simply, quickly and easily that the operation requires less time than the description. My last six cases were done with this instrument, and so far I have every reason to be satisfied.

The especial points of this needle to which I desire to ask attention are the oval-shaped point, and cutting edge, with the *large eye*. This large, elongated eye renders a silk loop unnecessary, as the ligature can be easily threaded into it at the second step of the operation.

747 Madison Avenue.

The Dyspnœa of Asthma, and the Influence of Nitrites upon it.—Dr. Thomas R. Frazer, of Edinburgh, in *The American Journal of the Medical Sciences*, for October, records a clinical study of the cause of asthma, and the influence of nitrites upon it. He establishes the view that the dyspnœa of asthma is caused by spasm of the bronchial muscles, and points out the value of the nitrites in its relief, and that the best therapeutic effects are not obtained by the inhalation of nitrites, but by their administration through the stomach. The facts seem to justify the assertion that their administration in this manner in asthmatic dyspnœa or orthopnœa is entitled to rank as one of the most valuable applications of pharmacology to the treatment of disease, an application at least as valuable as that in the painful angina of aortic disease, to which nitrites are at present almost restricted.

Progress of Medical Science.

Absorption by the Skin.—Dr. Ritter has given the question of absorption of lanolin through the skin a careful experimental trial. He found that when a ten per cent. ointment of potassium iodide and sodium salicylate in lard was rubbed into the skin, these substances were not absorbed, while through an application of an ointment of salicylic acid the characteristic reaction by chloride of iron could be proved in the urine (*Berliner klinische Wochenschrift*). This different effect Ritter explains by the fact that salicylic acid injures the continuity of the skin and is thus absorbed. A similar result was obtained when lanolin was used as a constituent of the ointment. According to Ritter, Liebreich's experiments are not convincing, because Liebreich only used such substances as led to absorption by injuring the continuity of the skin. By further experiments on the absorption of fluids, he came to the conclusion that it only takes place when the continuity of the integument has been interfered with.

The Endometrium in Disease of the Uterine Appendages.—Dr. Czempin has recently published some observations on the relation of the uterine mucous membrane to diseases of the appendages. He compares primary disease of the endometrium, set up by gonorrhœal infection or puerperal sepsis, which enter the uterus from without, with secondary disease, the result of chronic affection of the appendages (*The British Medical Journal*). In physiological processes a strong relation between the tubal and uterine mucous membranes can be observed, as in the formation of a uterine decidua in tubal pregnancy. A direct extension of inflammation from the tube to the uterus cannot be so readily proved during life. In relation to this subject, the sudden attacks of hæmorrhage observed in diseases of the appendages must be considered. The diseases where metrorrhagia is frequent are, first, chronic inflammation of the tubes and ovaries, often without symptoms until some circumstance causes aggravation of the disease; secondly, an exacerbation of old exudative parametritis; thirdly, pelvic irritation, especially such as may occur in the cicatrices of the pedicle after ovariotomy or salpingotomy; and fourthly, slow-growing tumors of the appendages, particularly pyosalpinx, and sarcoma or carcinoma of the ovary. Dr. Czempin rightly denies that endometritis must necessarily exist in all the cases, and must be the cause of the metrorrhagia. Clinical evidence shows that in many such cases no uterine symptoms existed before the other disorders were diagnosed. Brennecke traced the reflex hyperæmia and hyperplasia of the endometrium near the climacteric to the disturbance of ovarian functions. In cases under Dr. Czempin's observations, not far from the climacteric, however, where this symptom existed, metrorrhagia existed where the ovaries were healthy, and the tubes or broad ligaments diseased. Dr. Czempin distinguished special characters in the metrorrhagia, which accompanied chronic disease of the appendages. It was preceded by and commenced with very violent pain, on the cessation of which it continued to a moderate degree for some days. In all such cases inflammatory changes are found in the ovaries, tubes, or parametrium. On proper treatment of the primary cause the hæmorrhages disappeared; on the other hand, metrorrhagia from irritability of an operative cicatrix in the broad ligament, though more copious than the normal menstrual flux, was seldom preceded by any pain. Dr. Czempin traced this metrorrhagia to reflex congestion of the endometrium, due to irritation of the cicatrix, and did not believe that it was compensatory, in favor of the general organism, to menstruation, even after the removal of both appendages. The same observer discovered uniform thickening of the endometrium removed by scraping in cases of pyosalpinx, solid ovarian growths, and chronic oöphoritis, where the uterus was distinctly enlarged. In other cases the thickening of the endometrium was very slight; in others again there was no such change, though much metrorrhagia was present. In the latter the blood must have come from the hyperæmic tubal mucous membrane. The important researches of Dr. Czempin will throw some light on to the puzzling questions in relation to the direction in which inflammatory diseases of the female organs proceed. They must either be due to infection passing from the vagina through the uterine cavity and the tubes on to the surface of the ovary and into the peritoneum, or to infection entering the wound in the vagina or uterus and reaching the ovaries through the connective tissue, the peritoneum, or even the tubes being affected after the ovaries; or lastly, to some agency which causes primary inflammation of the ovary, the morbid process spreading from that organ to the tube, peritoneum, parametrium, and uterus. The subject is extremely intricate, and can only be solved by concomitant pathological and clinical study.

Contusion of the Abdomen, with Rupture of the Intestine.—The operative treatment of traumatic peritonitis, and of the injuries which cause it, is a subject of universal interest at present. In the October issue of *The American Journal of the Medical Sciences*, Dr. B. Farquhar Curtis, of New York, has studied the general subject by the aid of a series of 44 experiments upon dogs, and an analysis of 116 cases of rupture of the intestine, and of 33 cases of contusion of the abdomen terminating in recovery. Special attention was given to the symptoms of the first hours after injury, in the hope of rendering an early diagnosis possible, and to indicate the most promising methods of treatment. The practical results of the inquiry may be summed up as follows: The treatment of contusion of the abdomen should be purely expectant in the early stage, until symptoms of internal injury have appeared, or until the full extent of time in which they may be expected has passed. Explorative laparotomy at this time is admissible. When symptoms of uncontrollable internal hemorrhage or serious visceral injury appear, laparotomy is indicated; but, when the diagnosis is uncertain, the operation should always be begun as an exploration. Great collapse is an absolute contraindication to all operative interference. When rupture of the intestine is found, the best method of treatment is to secure the injured gut in the abdominal wound, and form an artificial anus. This can be easily relieved by a later operation, when the patient has recovered his strength.

Diagnosis of Beginning Carcinoma of the Cervix-Uteri.—Dr. Stratz, in an article on this subject, says that the perfected technique of the operative treatment of cancer of the uterus has rendered its cure possible, provided it is seen at a sufficiently early stage. It is, therefore, important to be able to make a diagnosis early. Even if certain symptoms, as profuse menstruation, leucorrhœa, pain, hemorrhage following coition, with the exclusion of other causes point to carcinoma, still the difficulty of distinguishing beginning cancer from erosions will always exist. Ruge and Veit recommend the excision of a piece of the erosion for microscopical examination, and by this means making a diagnosis. But even microscopically, it is possible to recognize certain characteristic appearances which are peculiar to carcinomatous erosions. He gives four particular important signs: 1. The diseased surface is everywhere sharply separated from the sound tissues; it nowhere gradually changes from one to the other. 2. A difference in level between the diseased part and the healthy can always be recognized. 3. The cancerous portions have always a yellowish tint. 4. The malignant spots show small, yellowish white, glistening raised points, at least in certain places.—*The Boston Medical and Surgical Journal*, September 1, 1887.

Viewing the Cavity of the Bladder.—From an article on tumors of the bladder by Dr. Davis, of Holyoke (*Boston Medical and Surgical Journal*), we learn that Dr. Nitze, of Berlin, has devised a method of exploring the cavity and inner surface of the bladder by the sense of sight. This is made possible by an ingeniously arranged electric light, so introduced that it may be said to be combined with an endoscope, the inner surface being as distinctly seen as though it were examined piecemeal by the light of day after removal from the body. The bladder is made to contain a certain quantity of transparent fluid, thus opening the folds of the mucous membrane, and presenting all portions of the mucous surface to view. The field at once visible is as large as a silver dollar, and is described as much resembling the image of the fundus of the eye when seen with the ophthalmoscope. By changing the position of the mirror in this instrument or kystoscope, as named by Nitze, the entire surface is readily and quickly seen, and any abnormal condition easily recognized. By the use of cocaine its use is rendered painless, and no other anæsthetic is necessary. The danger from heat resulting from the lamp in use is overcome by the circulation of a current of cold water. Nitze cites cases where his method of examination has succeeded in discovering tumors which were removed, and he is confident its more general use would make earlier diagnosis possible, and so save valuable time. At the Medical Society of Berlin, Professor Von Bergmann reported a case of tumor of the bladder, describing its symptoms, diagnosis and removal. In this case Nitze demonstrated to the satisfaction of Von Bergmann the practical working of his instrument, the latter speaking of it in terms of much praise, as being easily introduced and not distending the urethra or neck of the bladder more than a large-sized catheter, and in this case not occasioning any hemorrhage. If we accept the statements of Nitze and Von Bergmann, we shall be forced to believe that most incisions and severe proceedings for purely diagnostic purposes are soon to be laid aside, and the kystoscope is to reveal to the eye of the diagnostician the actual state, the size and shape of stones or tumors being readily seen and appreciated.

Hemorrhages from the Unimpregnated Uterus.—Dr. Hirton has made a study of this subject, which has led him to publish the following (*The Glasgow Medical Journal*): He believes the uterus and Fallopian tubes, including their fimbriated extremities, are erectile under excitement—the uterus under sexual excitement as well as menstrual, and the Fallopian tubes under ovarian excitement or during ovulation. In the majority of the lower mammalia there is no bloody manifestation at the menstrual period, but in many the uterus is relieved at times by the secretion of clear Nabothian mucus. Civilization has indirectly something to do with this. Some of the lower domesticated animals have bloody menstruation, as, for instance, rabbits kept in a warren for several generations and fed on rich food; also the sow and elephant for similar reasons. Again, some tribes of monkeys in India and elsewhere menstruate pretty frequently during the warmer months. In the colder countries of Europe, where the inhabitants lead quiet, unexciting lives, the females often do not menstruate until about eighteen, and sometimes not until many months after marriage, or even until after the birth of the first child. In South Africa, at a latitude where the winters involve comparatively cold weather, there exists a race inhabiting pits or excavations beneath the surface of the ground, and whose habits and intercourse generally differ little from those of the lower animals. The females of this race have only irregular periods of menstruation, and at the first blush of womanhood give out only abundant mucous secretion, as in the lower animals. It is only when indiscriminate intercourse has taken place for some time that blood appears, and then merely in comparatively small quantities. The menstrual flow cannot be said to be the direct effect of ovulation, inasmuch as it may be induced by other causes—*e.g.*, strong emotions, more especially those of joy; sexual excitement in the newly married; a day or two after operations in the abdomen, etc. The flow is also liable to be arrested by nearly as many and varied causes. The more you study the uterus as regards its hemorrhages, the more you are convinced that it behaves exactly like an erectile organ. Excessive joy may arrest the menstrual flow for some hours, to be succeeded in a few hours by a corresponding increase. As long as the influences that act upon the uterus are emotional—that is, act through the nervous system—the disturbance of its circulation is only attended by temporary evil results, but if along with these, or apart from them, you introduce other elements of disturbance of the circulation, you then have pathological hemorrhage. These other elements are divided into two classes—(1) those of disturbance to the egress of blood from the uterus, and (2) those conducive to obstruction to the venous return. It is this latter class that the author chiefly alludes to. Taking into consideration the anatomy and structure of the uterus and the ovaries, especially regarding their vascular supply, it is evident that their vascularity is subject to a wide range of tension. The veins of the venous plexus around the cervix, and especially below the ovaries, are unsupported throughout their course. They are also practically without valves, and their walls are very thin. In the upright position there is considerable resistance to the return of blood through these veins, whereas in animals the horizontal position favors the return. If, in addition to this, there is disease of the liver, heart, or lungs, the tension on the venous plexuses is markedly increased, and it is easy to understand that rupture of one or other of them should occasionally take place. Indeed, it is marvellous that it does not happen more frequently than it does. The main contention among various authorities regarding these hemorrhages is, whether the blood is exo-peritoneal or endo-peritoneal in its first instance. Of course the blood is endo-peritoneal in cases of rupture of the uterus or Fallopian tubes, as in tubal pregnancy. In cases of uterine hæmatocele, however, formed during labor, the author has determined that the peritoneum is capable of considerable tension and elasticity, and that the blood was exo-peritoneal.

Primary Malignant Degeneration of the Kidney in Infancy.—Primary malignant degeneration of the kidney is most frequently met with at the two extremes of life, infancy and old age. To the study of it as it appears in the first period, Dr. Longstreet Taylor, of Cincinnati, contributes an article, based on the study of 144 cases, in *The American Journal of the Medical Sciences* for October. Eminent authorities, both in America and Europe, have expressed the opinion that it is unjustifiable to remove degenerated kidneys in infants, but these same authorities for the most part advise the removal of sarcomatous kidneys in adults, their conclusion being based upon the statistics of the operation. A critical examination of the cases of this operation is, therefore, in place, in order to determine whether or not their verdict should be final. After a careful consideration of this question Dr. Taylor expresses himself as decidedly in favor of the operation, and thinks that if made when the tumor is still small, its results in the percentage of permanent recoveries will compare very favorably with those of malignant degeneration of other organs. It has so far succeeded in lengthening the lives of ten children, and of saving some of them. There is every reason to hope that in the future early diagnosis and early operations will show a much larger percentage of cures. As in all other malignant tumors, an early removal is necessary to success, but even late operations may lengthen life and possibly save it. He advises that explorative incisions be made whenever it is possible. And if extensive adhesions or visible metastastic growths forbid further interference, then desist from the operation.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 22, 1887.

INFECTION AND CONTAGION FROM A NEW POINT OF VIEW.

THE work of the bacteriologist and pathologist is greeted with favor, for one reason at least, because it gives us clearer and simpler conceptions of the nature of disease. It may be that, in later years, we shall see a decadence of the micro-organism in its relation to this subject; but at present it is certainly firmly intrenched, and he is no pathologist who attempts to ignore it. Besides, our present working hypotheses are the better for it. We are particularly grateful to the micro-organism for simplifying the current ideas regarding contagium, miasm and infection. Medical text-books, as a rule, teach that there are three classes of infectious diseases—the contagious, the miasmatic, and the miasmatic-contagious. In the first, the specific poison or virus develops in the body, and, in its active state is eliminated and passed on to another body, exciting in it disease. Measles, scarlet-fever, and small-pox illustrate this type. In the miasmatic diseases, the virus develops outside the body, and either does not multiply in the flesh, or at least is not eliminated from it in a state capable of producing infection. Malaria illustrates this type. In the miasmatic-contagious diseases, such as cholera and typhoid fever, the poison multiplies in the body; when eliminated, however, it is not at first active, but requires time and suitable conditions for the development of the specific infectious principle. The hypothesis of miasmatic-contagious disease was framed to suit the natural histories of cholera and typhoid. It has never had any solid evidence in its support; and Dr. Wm. H. Welch, in a very able and suggestive address delivered before the Medico-Chirurgical Faculty of Maryland, at its last meeting, shows the weakness of the current argument used in support of it.

First of all, it has been found that the class of micro-organisms to which the cholera and typhoid germs belong do not undergo any transformations in virulence, and do not acquire in growth any infective properties not originally possessed. On the other hand, bacteriologists generally regard bacteria as especially potent when fresh from the bodies of infected animals. Even the theory that the morbid symptoms are produced by ptomaines does not help, for fresh stools ought to contain the largest amount of these products.

The great argument in favor of the miasmatic-contagious view, however, is that persons do not catch cholera or typhoid as they do small-pox or scarlet-fever. It is inferred, therefore, that the germ is discharged in an inactive form. But it is not necessary to assume this. Dr. Welch calls attention to the fact that the germs of cholera and typhoid have different modes of life to those of variola, etc. The cholera germ, for example, is eliminated only by the intestines; hence, however active, direct contagion can only occur through the stools. But bacteria are, as is known, never lifted by currents of air from the surface of fluids or from moist surfaces generally. Hence one might be in the closest proximity to the infected dejecta with perfect safety.

Cholera bacteria can only invade the air in a dry condition; but dry air quickly kills them. Again, the germs must be taken into the alimentary canal in order to cause infection, and here again special conditions are necessary. It is, therefore, perfectly easy to account for the apparent inactivity of choleraic or typhoid excreta without assuming that the germs are obliged to undergo a development. On the other hand, the view that these germs are active explains many cases in which direct and immediate infection has occurred, while it does not militate against the known facts that epidemics of the so called miasmatic-contagious diseases do not as a rule spread by direct contagion. Their mode of spreading, however, is dependent upon the peculiar life history of the germ, and its mode of exit and entrance into the body, not upon its inactivity when first eliminated.

The new view of this subject from the bacteriologists' standpoint, therefore, involves an abandonment of the terms miasmatic and miasmatic-contagious. Every infectious disease has a contagium. In some this contagium multiplies in the body, is thrown off by various channels, and is taken into the system of others by various channels. These are the contagious diseases, as ordinarily described.

In other cases the contagium is both taken into the body and eliminated, only by one, or at most two channels; hence such diseases, as a rule, do not cause direct infection, they form the so-called miasmatic-contagious diseases.

In still other cases the contagium invades the body, but apparently is not eliminated at all, but is destroyed; these form the so-called miasmatic diseases, of which malaria is the type.

Following out this view of the matter we should have the following rearrangement:

1. Infectious diseases having a germ which enters the body and is eliminated by several channels, equivalent to the old contagious disease-class. 2. Infectious diseases having a germ entering and eliminated by a single channel, the so called miasmatic-contagious class. 3. Infectious diseases having a germ which is destroyed in the body, the so-called miasmatic class.

It will be seen that the old terms lose all their significance by this new interpretation of the pathogenesis of infection. The classification may be retained for convenience sake, but new names for the classes are needed.

THE PHYSIOLOGY OF DECAPITATION.

The physiological study of decapitation is truly the grimmest and most repulsive of all departments of inquiry. The experiments of Brown-Séquard upon the heads of dogs showed that, by injecting arterial blood, the muscles reacted, the eyes moved, and evidence of sensation was present. Brown-Séquard's statement, that a similar revival of consciousness could be brought about in man, was almost realized in April last, by experiments made on the head of the murderer Gamahut. Under the influence of transfused blood, the face regained its color, the eyelids partly opened, and the lips quivered for a few seconds, as if trying to express some emotion. The inference was drawn that consciousness remained, or would return to the decapitated head as long as there was a sufficient supply of blood. Some further experiments were recently made by MM. Paul Regnard and Paul Loye (*Gazette des Hôp.*, July 3, 1887) upon the head of a criminal executed at Amiens, June 15th. In this case the head was obtained and examined within two seconds after decapitation. The face still preserved its color, the features were immovable, the eyes widely open, the mouth convulsively closed. For five seconds, by touching with the finger the exposed cornea, a quick closing of the lids could be brought out. This was the only reflex obtainable, and this disappeared at the end of five seconds. A bright light before the eye did not cause any movement of the pupil, nor did pinching or pricking the skin cause any change in the physiognomy. Direct stimulation of the cut spinal cord did not cause any movements either in the head or trunk. At the end of four minutes, the closed jaws began to relax, and the eyelids to droop. At the end of twenty minutes an autopsy was made. The heart was found to be still beating, and the pulsations continued for five minutes more in the ventricles, and for ten minutes in the auricles. After decapitation, therefore, the human heart may continue to beat for half an hour.

The experiments in this case only go to show what was already known, that in decapitation consciousness ceases entirely with the blow on the neck. The shock itself of the section is sufficient to cause this, while the immediate draining away of blood prevents a return of consciousness.

THE DOCTOR'S GIG.

We all admit that medicine is the most progressive of sciences. But the reason for this, though simple, is not so generally known, and we shall take pleasure in unfolding it now, with some attention to detail. The physician spends one-sixth of his life in his carriage, and it becomes simply impossible that there should not be steady intellectual advance along with so much corporeal progression. This is easily shown to be the case. The doctor grows wiser with years beyond other learned classes. In the medical cult age always receives recognition; for the doctor who has practised twenty-five years, and ridden his one hundred thousand miles, has, just by reason of such extensive locomotion anteriorly, gained not only physical vigor but mental expansion, to say nothing of gluteal callosity and experience with wagons and the ways of the world. It is, no doubt, more than a coincidence that to the doctor's equipage there has gradually come to be applied the term "gig." Now, Johnson defines gig as a wanton girl, but the ordinary uses of the word are different; and, so far as applied to things medical, we believe its true etymology to be from the Greek *gignosco*, to know.

It has been said by historians and orators that medicine made little progress until seventy-five years ago, and it was about this time that medical men began to adopt the gig, which is another evidence of its motive power in human progress. Hippocrates had to make his calls on foot, hence his limitations. If his genius had been supplemented with an office-boy and a modern conveyance, medicine now would be luminously beyond its present state.

All of the foregoing reflections are pertinent to a sober consideration as to what is the best kind of carriage for the doctor's use.

In England, where the roads are good, a considerable variety of vehicles seem to be adopted by the profession. On the Continent, a two-wheeled gig, with hood, is in much favor among country doctors. In earlier times it was known in New England as a chaise. "This sort of chariot is affected," says a writer, "by a kind of pitching movement to and fro across the axle, which well entitles it to the name of a 'noddy.'" "To ride in such a carriage," he adds, "cannot be numbered among the things that appertain to glory; but I have no doubt it may be useful in liver complaint. Thence, perhaps, its wide popularity among physicians."

This chaise or "noddy" has been very generally abandoned in this country, for, though agreeable to the rider, it is hard upon the horse. The popular and almost universal vehicle is the buggy with a top, which has been christened improperly a gig. The doctor's gig, so-called, is not a handsome vehicle, and no one drives in it for the purpose of illustrating the sensuous side of the carriage-builder's art; but it seems to be generally accepted as suiting the purpose. The physician who desires true elegance and comfort in the city uses the brougham.

But the ideal vehicle for the physician has yet to be evolved. He owes it to his profession to adopt something less shoppy and inartistic than the gig, which should be given over to builders, plumbers, drummers, and the cold world of business generally. In its place we need a something which shall show more than the hard lines of a purely utilitarian conveyance. We trust that some genius will discover a substitute for the present doctor's gig.

THE CONDITION OF THE CROWN PRINCE OF GERMANY.

Dr. Robert C. Miles, clinical assistant of Sir Morell Mackenzie, sends the following cablegram to The Medical Record:

"The present scare concerning the Crown Prince of Germany is quite unfounded. He had an attack of subacute laryngitis, occasioned by a cold while at Tobloch. He has now entirely recovered, and there has been a steady improvement in his condition since his arrival in Italy.

News of the Week.

To Secure Longevity.—A little while ago it was distilled water and phosphoric acid, now it is common salt that surely leads to centenarianism. Dr. Burggraëve, of dosimetric fame, has, says the Paris correspondent of the *American Practitioner*, just published a work on human longevity in which he indicates the means by which a human being may live beyond a hundred years. It consists simply in the "rational employment" of common salt, which, according to this author, is the preservative against all diseases. It lengthens life by keeping off disease. The dose necessary in ordinary times is 3 v. daily. Burggraëve himself uses additional means to prolong his life. He takes every night on going to bed, as a prophylactic measure, one dosimetric granule of digitaline and one granule of arseniate of strychnine, one milligramme of each, which he repeats once or twice more in the twenty-four hours, according to how he feels. Besides these granules he takes every morning a small dose of granulated sulphate of soda, by which means the bowels are kept free and the blood relieved of its acridity. By the daily ingestion of the granules above mentioned the vital force of the organism is duly kept up. Dr. Burggraëve is now over eighty years of age, and still looks strong and hale. He enjoys a good table and makes use of the best of wines.

A Midwife Practicing Medicine.—Bertha Brown, a New York midwife, was arrested on complaint of an agent of the Medical Society of the City of New York, for practicing medicine without a diploma. The Special Sessions sentenced her to pay a fine of $250, or go to jail for 250 days. She appealed, and her appeal was allowed on the ground that by the new medical law of April, 1887, all persons were allowed until October 1st to file their diplomas.

The Automatic Apothecary, and the Real One.—Some ingenious druggist has utilized the popular craze over automatic machines for weighing and selling wall articles, etc. A machine is so devised that, by dropping in the proper coin, one can take out a remedy for his constipation, corns, biliousness, or other minor ailment. The possibilities of automatism in the treatment of human ills thus seem to loom up in very large proportions, and the automatic doctor may be one of the creations of the future. The worst enemy to such perspective simplifications of medical art, however, will be the druggist, who is bound to prescribe with more frequency, though perhaps with less intelligence than any mere instrument made of weights and springs.

Another Cure for Phthisis.—A month rarely passes without some new cure for consumption being offered. Among the latest is that advocated by M. Garcin, before the Paris Academie de Medicine. His method consists in the inhalation of fluorhydric acid. The patient remains for an hour daily in a cabinet of six cubic metres capacity, the air of which is saturated with fluorhydric acid. Among 100 phthisical patients, 35 are reported cured, 41 improved, 14 stationary, 10 dead.

The Diagnosis of the Case of the Late Gov. Bartlett, of California.—Dr. M. E. Zakrzewska, of Boston, writes, as a friend of Dr. C. Annette Renkel, that Dr. Renkel never made a diagnosis of Gov. Bartlett's illness from abscess of the kidneys as reported in the papers, but of a growth in the bladder. An autopsy was not thought necessary to confirm this diagnosis.

Medico-Surgical Society of French Canadian Physicians.—As the result of a Convention of French Canadian Physicians of New England, held in Worcester, Mass., on the 15th and 16th ult. at which forty Physicians were present, a "Medico-Surgical Society" was founded with the following officers: President, V. Mignault, M.D., of Lawrence Mass; 1st Vice-President F. D. Fontaine, M.D., of Worcester Mass.; 2d Vice-President, F. St Germain, M.D., of Warren, Mass; Recording Secretary, E. Sirois, M.D., of Three Rivers, Mass.; Corresponding Secretary, J. H. Palardy, M.D., of W. Gardner, Mass.; Treasurer, Benj. Fagnant, M.D., of Springfield, Mass.; Librarian, F. R. Patoël, M.D., of Holyoke, Mass.; Assistant Corresponding Secretary, N. Malo, M.D., of Danielsonville, Conn.

The death of Dr. G. W. Mason, of Bloomington, Ill., Oct. 11, 1887, occurred in consequence of an earnest devotion to the duties of his profession. He returned from the International Congress somewhat fatigued, and suffering from a slight rhinitis. While in this condition, he went September 29th to perform intubation, in a case of diphtheritic croup. On Saturday, Oct. 2, he again performed intubation on another case. The following day, diphtheritic membrane was visible in his throat, and he died of malignant diphtheria, Saturday, Oct. 8th. Dr. Mason was an able and scholarly man, and but thirty-seven years of age.

Discovery of the Specific Germ of Texas Fever.—Dr. Frank Billings, of the Patho-Biological Laboratory of the Nebraska State University, states (*American Lancet*) that he has certainly discovered the germ of Texas cattle fever. He says: This germ belongs to that class of septic germs represented by our swine-plague, the "wild seuche" and "schwino-seuche" of Germany, and rabbit septicæmia. It is a bacterium. It colors at its poles, and has a clear or non-coloring middle piece to its body. Like the H. C. germ it has motility in hanging drop cultures and also in the blood serum from the original blood of a diseased animal. It cannot be distinguished from the H. C. germ under the microscope, or in its growth on agar-agar, but differentiates itself very sharply by its growth on potatoes, having a delicate straw color, while the H. C. germ has a muddy coffee color—"boarding-house coffee color" a friend suggests. In gelatin I have not yet tested it on account of the obstacles of the prevailing temperature.

Death from a Skunk Bite.—Dr. Geo. W. Howard reports (*Nashville Journal of Medicine and Surgery*) the case of a boy of eight who was bitten slightly on the hand and face by a skunk. A month later he developed symptoms of pharyngeal spasm, and died.

The Treatment of Puerperal Convulsions in the Vienna Hospital.—The method of treating this complication is to keep the woman under the influence of chloroform and to promote copious perspiration by a full-length hot bath. They know nothing of elaterium or

other drastic cathartics with which we reduce the dropsy, and carry, in some cases at least, the woman along to safety.—*Cor. Maryland Medical Journal.*

We regret to have to chronicle the death, on the 7th ult., of Dr. James A. Gray, of Atlanta, Ga., one of the editors of the *Atlanta Medical and Surgical Journal.* Dr. Gray was only 37 years old.

The methods of cleansing the hands in the obstetrical wards at the Vienna Hospital are described as follows by Dr. C. W. Earle(*Maryland Medical Journal*:) In Spaeth's wards, one's hand's are cleansed by the use of a powder made by grinding up bitter almonds, both shells and kernel. It seems to possess great cleansing and absorbent properties. In Prof. Braun's touch course, before all examinations, the hands are scrubbed with a brush in soap and water, then dipped in a solution of permanganate of potash, and finally into a solution of muriatic acid.

The French and the next International Medical Congress.—It is not easy to please everyone in arranging International Congresses. A correspondent of *L'Union Médicale* thus expresses his feelings in regard to visiting Berlin in 1890: "Before adjournment the International Congress decided to hold its next meeting in Berlin. Although possibly the German delegates to the Congress did not outnumber the French, yet they found in America a number of partisans in their favor in Americans of German origin. At Copenhagen the protestations of French delegates, especially of MM. Trélat and Verneuil, were opposed to Berlin as the place for the next meeting; this obstacle did not exist this year. As but a small number of Frenchmen were at Washington, the capital of Germany was chosen by necessity. Will we go to Berlin in three years? I admit that I should prefer to go there in such a peaceful manner, rather than be obliged to traverse a route strewn with the bodies of German and French soldiers. But do not ask me my real desire."—*Medical News.*

From another quarter we have a similar expression of opinion.—It is greatly to be regretted that our French brethren take the matter so badly. The *Progres Medical* expresses great disappointment and chagrin, sentiments in which *L'Union Medical* seems fully to share, while the *Journal de Medecine de Paris* says that Berlin was chosen through the influence of Professor Martin, and that the choice is a "veritable insult" to France. The wish of the French physicians to have the meeting in Paris in 1889, was especially strong, because at that time the International Exposition is to be held there. There was certainly no slight intended in this matter, and we trust that all ill feeling will have disappeared when the time of meeting comes.

Dr. Milton Josiah Roberts has resigned the professorship of Orthopedic Surgery and Mechanical Therapeutics in the New York Post Graduate Medical School and Hospital.

Chronic Recurrent Fever—An Alleged New Infectious Disease.—Professor Ebstein recently read (*British Medical Journal*) before the Göttingen Medical Society a paper on "A Case of Chronic Recurrent Fever: a New Infectious Disease." The illness began in the patient, a youth aged nineteen, without any distinct cause, and the time of onset was not clearly marked. The only symptom of the disease was the fever. The patient has feverish attacks, which cease after a certain time, and recur after a definite interval, so that pyrexia and apyrexia alternate with a regularity which is not seen in any other disease. Each attack lasted on an average from thirteen to fourteen days, the apyrexia from ten to eleven days, so that from the height of one attack to the corresponding period in the next the interval was about twenty-four days. The temperature rose gradually in each attack above 40° C., sometimes to 41° C., and even higher, then it gradually fell below normal. The blood was normal, showing no increase in the number of white corpuscles and no bacteria. The lungs and the digestive organs seemed to be quite healthy. There was neither albuminuria nor glycosuria. The spleen was enlarged. Arsenious acid, quinine, and antifebrin were given, together with brandy as a cardiac stimulant, but treatment had no effect. P. K. Pel, in Amsterdam, has seen one case of the same disease. He at first thought it was phthisis, then an irregular form of typhoid fever. The patient died in the fourth attack. The *post-mortem* examination showed that the spleen and the retroperitoneal, mesenteric, and bronchial glands were enlarged. He therefore believed the disease to be pseudoleukæmia. Professor Ebstein, however, thinks that we give the same name (pseudoleukæmia) to two different diseases, of which one has a febrile course, while in the other there is either no fever or an irregular one. Typically only the latter should be called pseudoleukæmia; the former he proposed to call "febris recurrens chronica," and places it in the category of infectious diseases.

The Birth rate in France.—The French population returns for 1886 have just been issued. The births exceeded the deaths by 52,560, the smallest excess known of late years.

The Misuse of Marriage.—Under this title a London author has written a book, the chief object of which is to show the dangers of marriage between elderly men who have led immoral lives, and young girls. There are moral, physiological and pathological reasons which fully support the view taken by this author. And the physical evils which may result are sometimes transmitted to the children. Fortunately, we believe that such misuse of marriage is not common in this country.

The Babies of this City are likely to be well looked after this winter. Besides the Babies' Ward, at the Post-Graduate School which has been in successful operation for several winters, a Babies' Hospital is being organized at a house up-town.

Venous Murmurs and Anæmia.—Dr. A. Weil in his work, "Auskultation der Arterien und Venen," claims that venous noises are valueless as evidences of chlorosis and amæmia. Apetz, in a recent article on a similar subject in *Virchow's Archives*, comes to nearly the same conclusion. The venous murmurs in the internal jugular veins, for example, he finds to be dependent mainly upon the youth of the patient. A venous hum in the neck of a person under twenty may be perfectly physiological.

Reports of Societies.

NEW YORK STATE MEDICAL ASSOCIATION.

Fourth Annual Meeting, held in New York, September 27, 28, and 29, 1887.

(Continued from page 496.)

THURSDAY, SEPTEMBER 29TH—THIRD DAY—MORNING SESSION.

THE TREASURER, in his report, said there was a balance of $240 in the Treasury, in addition to a building fund of $465.

THE ADDRESS ON MEDICINE

was then delivered by DR. JOHN CRONYN, of Erie County. The orator took a general view of the field of medicine, and referred to the part played by the specialists in bringing the science to its present degree of perfection. He said that those who commenced the study of medicine should be previously fitted for their work by a good general education, they should be imbued with a reverent love for their profession, and should have an ever present lively sense of its great responsibility resting upon them.

DR. B. L. HOVEY, of Monroe County, then read a paper with the title

COLD AS A THERAPEUTIC AGENT.

He first alluded to the history of therapeutic measure. He had found it especially serviceable in the management of asthenic fevers, but he thought it was a dangerous remedy unless great caution were taken in the selection of proper cases. The temperature of the bath, when this method is employed, should, as a rule, not be less than 65° or 70° F., and the patient should not be kept in it longer than from seven to ten minutes. Among the affections in which he had employed cold in one form or another, were typhoid fever, sun-stroke, gastritis, hæmatemesis, and other forms of hemorrhage, Bright's disease, etc.

DR. NELSON L. NORTH, of King's County, followed with a communication entitled

THE SMALL-POX IN BROOKLYN; DEFECTIVE ISOLATION AND DEFECTIVE VACCINATION.

He said that the late epidemic of small-pox in Brooklyn, extending over a period of more than a year, had started from one concealed case in the person of a Polish immigrant who had landed at Castle Garden. He did not criticise the system of vaccination and isolation, as practised in Brooklyn, because it was necessarily worse than others, but simply because he knew more about it. He spoke more particularly of the interference of politicians with sanitary matters. He suggested the passage of more definite laws giving power to the health officers to control of patients suffering from contagious diseases, as well as the more rigid carrying out of the laws and ordinances already in force. He looked upon the small-pox hospital as a remnant of barbarism, and believed that there could be isolation without removal. He urged the employment of good nurses and good physicians who could take care of their patients and treat them rationally, and not leave them to live or to die as the case might be. The records showed that a greater proportion died of those sent to the hospital than of those who remained concealed at home.

It was a popular belief that many were sent to the hospital who had not the disease, but contracted it there. It was no wonder, therefore, that the friends tried to conceal their sick from the health officers. In closing, the speaker referred to the necessity of thorough vaccination, and the importance of using only fresh and pure vaccine.

DR. HENRY C. VAN ZANDT, of Schenectady County, then read a paper entitled,

SPECIALISTS,

in which he condemned the tendency of physicians to limit their practice and their knowledge to a single class of diseases. The general profession, he said, was made to suffer for the errors of the specialists. He insinuated that it was apt to be the unsuccessful general practitioner who became a specialist.

THE COMMITTEE ON NOMINATIONS

then made their report, in accordance with which Dr. John Cronyn, of Erie County, was elected president.

DR. THOMAS MANLEY, of New York, then presented a paper entitled,

EPITHELIOMA OF THE VULVA.

The speaker said that, although little mention was made of this affection in the books, he thought it could not be very rare, for he had seen two cases within five years. In both he had operated, with the result of arresting the progress of the disease.

AFTERNOON SESSION

The order for this session was a

DISCUSSION ON PLACENTA PRÆVIA.

DR. GEORGE TUCKER HARRISON, of New York, opened the discussion. He first spoke on the importance of a knowledge of the changes occurring in the cervix in the latter part of gestation, and during labor. The former belief on this point seemed to rest on a solid basis, but the arguments recently brought forward by Randel certainly appeared to overthrow these in a measure. The uterus was divisible into the thickening and contracting upper part, and thinning and expanding lower uterine segment, including the cervix. During labor the lower uterine segment was essentially passive, the upper part exhibiting active contractions, the boundary between the two being denominated by Schroeder as the ring of contraction.

The important symptom of placenta prævia was, of course, hemorrhage, the source of the bleeding being the placental site, and the cause being the separation of the placenta. The main indications in treatment were to guard the patient against the two dangers of hemorrhage and sepsis. The special liability of women who were the subjects of placenta prævia to septic infection was explained by the fact that the placental site was lower, and also that lacerations were frequently a result of the measures employed in treatment, the agent of infection being the examining finger of the accoucheur. Anæmia further favored septicæmia.

The author advocated the bipolar method of version introduced by Braxton Hicks, as the best means of answering the indications. Zweifel's method of avoiding perforation of the placenta in central implantation was especially commended. He hoped that in the near future some means would be devised to prevent the great infant mortality resulting from this complication of labor. Zweifel's method might be of service here; and doubtless much good would come from improvements in antiseptic procedures, which would enable the accoucheur to use the vaginal tampon, and rupture the membranes without perforating the placenta.

The first question proposed for discussion was:

IN CASES IN WHICH THE PLACENTA IS PRÆVIA, WHAT ANATOMICAL AND PHYSIOLOGICAL FACTS EXPLAIN THE HEMORRHAGE OCCURRING DURING PREGNANCY, AND WHY IS HEMORRHAGE UNAVOIDABLE DURING MISCARRIAGE OR LABOR?

The discussion on this question was opened by DR. CHARLES C. FREDERICK, of Erie County.

The speaker reviewed briefly the anatomical and phys-

iological facts which were supposed to account for hemorrhage in placenta prævia. He did not believe that hemorrhage was unavoidable during labor or miscarriage.

Dr. Isaac E. Taylor, of New York, said the obstetrician based his views upon the teachings of the anatomists and upon what he learned by touch during delivery. He had already expressed his views on this subject in a brief paper read before the New York Academy of Medicine in 1862. He demonstrated by touch alone that the cervix uteri did not coalesce with or become absorbed into the body of the uterus during the progress of gestation. The cervix had no special physiological function as had the body; it was passive, and remained so until the time of labor. It was prepared physiologically to dilate and expand in order to permit of the delivery of the child, just as the body of the uterus was prepared to contract and thus accomplish the delivery. He had held these views for the past thirty-five years, and had expressed them in the paper alluded to. They did not, however, receive the attention which they deserved at the time, and now they had recently been revived by Hoffmeier. All acknowledged that the cervix is anatomically distinct from the body; the placenta is therefore not physiologically related to the circulation of the cervix. The body of the uterus is the only proper place of attachment for the placenta during gestation. The hemorrhage which takes place during labor in cases of placenta prævia occurs during the relaxation of the uterus and not at the time of a pain.

Dr. Darwin Colvin, of Wayne County, discussed the second question, viz.,

IN THIS ANOMALY, WHAT IS THE SOURCE OF HEMORRHAGE, AND WHAT IS THE MECHANISM OF ITS ARREST?

The speaker referred to the difference of opinion entertained by authors as to the source of the hemorrhage. He said that he formed no definite opinion on the subject, and would not, therefore, devote much space to its consideration. He had had five cases of placenta prævia, and from his experience had come to the conclusion that the proper treatment was to induce labor at once, and not risk the life of the mother with the possible hope of saving the child. The responsibility was too great to temporize. He believed the life of the child was entirely secondary to that of the mother, and that an effort to save both by delaying the induction of labor would often result fatally to mother and child.

Cor. S. B. Wylie McLeod, of New York, said that, in his opinion, the source of the hemorrhage was the placenta, the uterine sinuses, or branches of the uterine artery or vein, or both, or all combined. Authors, however, were not agreed in their views on this subject. As to the means best adapted for its arrest, he would confine himself to a few measures only. The first and most essential thing was to convert partial separation of the placenta into total separation, and the hemorrhage would then generally cease. This gave an opportunity to the uterus to contract, and thus close the openings of the sinuses. Cold, ergot, etc., might occasionally be of service. The tampon could only temporarily delay the bleeding.

Dr. William T. Lusk, of New York, then discussed the question:

IF PLACENTA PRÆVIA BE DIAGNOSTICATED DURING PREGNANCY, IS THE INDUCTION OF PREMATURE LABOR INDICATED?

He thought that the accoucheur should proceed to deliver, if pregnancy had advanced to the seventh month, for the next hemorrhage might prove fatal. Abortion usually resulted from hemorrhage occurring before the seventh month, and the management of this does not differ from the management of abortion occurring from other causes. If hemorrhage begins before the child is viable, there is little hope of saving it by delay. In most cases the first hemorrhage is slight, but it should serve as a warning, and if the accoucheur's suspicions are confirmed, he should then not leave his patient until the delivery is accomplished. The practical results of the induction of labor in the hands of its advocates demonstrate its value. Strict antisepsis is a condition of success. Version is to be deprecated as it is attended by serious loss of infantile life.

Dr. Rollin L. Banta, of Erie County, opened the discussion on the fourth question.

DURING LABOR, WHEN THE PLACENTA IS PRÆVIA, WHAT MODE OF TREATMENT BEST SUBSERVES THE INTERESTS OF THE MOTHER AND CHILD RESPECTIVELY? IS THAT PLAN OF TREATMENT WHICH BEST CONDUCES TO THE PRESERVATION OF THE MOTHER'S LIFE INCOMPATIBLE TO A CERTAIN DEGREE WITH THE CHILD'S INTERESTS?

The speaker favored the method of Braxton Hicks, which, in his experience, most often proved effectual in saving the life of the mother. He had found less danger from hemorrhage than from infection, although he had always observed antiseptic precautions.

Dr. John Shrady, of New York, in continuing the discussion, said that he believed the percentage of maternal deaths which had been given as one in three, was too high, while the percentage of the infantile deaths had been under-estimated. The latter was much nearer 80 per cent. than it was 65. He could recall but four cases in his own practice, but they were not cases of central implantation. The watchword, deliver at all hazards, seemed, in the days of his pupilage, to have been passed all along the lines of the profession. The best chances of the mother, he believed, were in immediate delivery. But, still, it should be remembered that, in a certain number of cases of cervical lateral attachment the hemorrhage may cease spontaneously. In any case, he believed, the interests of mother and child did not, in any sense, conflict.

Dr. John G. Orton, of Broome County, discussed the last question, viz.:

AFTER CHILDBIRTH, IN PLACENTA PRÆVIA, WHAT THERAPEUTICAL MEASURES WILL MOST CERTAINLY GUARD AGAINST THE DANGERS OF HEMORRHAGE AND SEPTIC INFECTIONS?

In which he called particular attention to the benefit derived from friction over the nipples in the arrest of uterine hemorrhage.

Dr. William H. Robb, of Montgomery County, also discussed this point. He said the attendant should remove pillows from under the patient's head, secure firm and continued contraction of the uterus, and give at once fifty minims of the fluid extract of ergot, by hypodermic injection; if this failed, hot carbolized water should be injected well up into the uterus. In two cases the only means by which he had been able to maintain firm contraction of the uterus was by faradization. In such a case he would suspect laceration of the cervix, and, if the patient's condition admitted he would repair it at once. The uterus should be completely emptied and firm contraction should be secured as the best means of preventing infection. It might be necessary to inject hot carbolized water, and after that to throw iodoform up to the fundus. All lacerations should of course be disinfected.

Dr. James C. Hannan, of Rensselaer County, then read a paper on

ACUTE MANIA.

He repeated the history of a case in which there had been unusual difficulty in arriving at a diagnosis. The patient was a young man, and had rheumatic symptoms in addition to the cerebral manifestations.

Dr. Charles S. Allen, of Rensselaer County, then related

A CASE OF INTRA-RECTAL LARVÆ, WITH GASTRITIS, IN AN INFANT.

The author described in detail the patient's symptoms. Peculiar objects were found in the stools which, on microscopical examination, resembled the larvæ from the blowfly. He thought the food must have been the means through which the larvæ were introduced.

The session was then adjourned.

BRITISH MEDICAL ASSOCIATION.

(Special Report to The Medical Record.)

SECTION OF SURGERY.

Thursday, August 4th.

Mr. Laffan, of Cashel, read a paper on

THE TREATMENT OF SPINAL ABSCESS.

He said that in nearly all cases spinal abscesses were either opened or opened spontaneously. Authorities differed as to the advisability of opening them. Mr. Treves' plan was referred to, but Mr. Laffan said Mr. Treves did not propose to employ his method in disease of the dorsal vertebræ. He himself desired to extend it to them and to use it earlier in point of time. He would cut down on the bone before an abscess had had time to form, and provide for drainage. He described a case in which he had operated on a patient with abscess in the iliac fossa. He believed that the only chance of dealing with spinal cases was by "direct treatment" and by extending its use to suitable cases. It was not necessary to cut through the bodies of the vertebræ, but simply toward them, so as to provide for suitable drainage.

Mr. Illingworth, of Clayton-le-Moors, objected to the danger of the proposed method. He referred to the value of aspiration and described a successful case. He deprecated very early opening. In a case of his own he had aspirated ten times—each time withdrawing less pus. An abscess eventually formed in the thigh, but it was treated as an ordinary cold abscess and the patient recovered.

Mr. Walsham said Mr. Laffan advocated a very serious procedure. If the patient were kept at rest in the great majority of cases no abscess would form.

Mr. Frere referred to cases in which pus had been absorbed.

Dr. Gibney, of New York, preferred to let such abscesses severely alone. It was not an uncommon experience to see abscesses of large and small size disappear. It was safe to let such abscesses alone—certainly for general practitioners. He would open a certain number of a certain size.

Sir Spencer Wells, of London, then read a paper on

COMPARISON OF THE CÆSAREAN SECTION WITH PORRO'S OPERATION.

He said that formerly the comparison was between craniotomy and the Cæsarean section. Beattie, Montgomery, and others had argued the question. Ten years before his own student days that remarkable man, James Blundell, had (in 1828) said that the dangers of the Cæsarean section might be greatly lessened by the removal of the uterus, but it was not till 1869 that the operation had been performed (in New York). Porro had performed it in 1876. In 1884 Dr. Godson had brought forward a case of his own (successful as regards both mother and child), and had given particulars of several others in a paper read before the annual meeting of the British Medical Association. Of Porro's operation 152 cases were on record. Sixty-six women had lived and (excluding those who only lived a few hours) 96 children, thus making a total of 162 lives saved. Sir Spencer Wells said his own experience was limited to one case, which he described. He thought the danger to the mother was much less with Porro's operation than where the empty uterus was left, whether the opening in the uterus were closed with sutures or not.

Dr. Imlach, of Liverpool, said Sir Spencer Wells had wisely left the question open. We had gone on by a process of inversion. It was a wonder that the surgeon who removed Cæsar from his mother's womb had not done Porro's operation. He had done two himself; one child had lived. The same remark applied to myoma of the uterus. He thought we should in both cases be able to come to the Cæsarean section. Where, however, the condition of the organs would necessitate a repetition of the operation, no object was gained by leaving the reproductive organs.

Sir Spencer Wells dissented from the view that the Cæsarean section was more difficult than Porro's operation. He thought enucleation of a fibroma was very unsatisfactory.

Mr. Taylor, of Birmingham, then read a paper on

A CASE OF CHOLECYSTOTOMY FOR GALL-STONES, WITH REMARKS ON THE TREATMENT OF THE BLOCKING CALCULUS.

He remarked that one great difficulty in the operation of cholecystotomy was the removal of the stone. In the case he now described, there were several stones. One was wedged in the cystic duct, and he could only break off a piece from it. He did not venture to crush it from the outside. He stitched the gall-bladder to the edges of the wound, and washed it out with warm water. A rubber drainage-tube was employed. In fourteen days the stone returned into the gall-bladder. He subsequently found it loose in the gall-bladder, and quite soft. When grasped by forceps it broke down, and was readily removed. The three points to which Mr. Taylor desired to call particular attention were: 1, the use of warm water, which had been suggested to him in this case by its use in removing foreign bodies from the external auditory meatus; 2, the fact that some large calculi undergo changes and become soft; 3, the advantages of employing a special kind of forceps, which he exhibited.

Mr. Allingham, Jr., of London, then read a paper on

INGUINAL COLOTOMY; ITS ADVANTAGES OVER THE LUMBAR OPERATION, WITH SPECIAL REFERENCE TO A METHOD FOR PREVENTING FÆCES PASSING BELOW THE ARTIFICIAL ANUS.

Mr. Allingham remarked that the peritoneum was no longer held in awe. Inguinal colotomy possessed the advantage that respiration was not interfered with during the performance of the operation. The intestine also did not fall away from the abdominal wall, as it did from the loin in the side position. The passage of fæces below the artificial anus was obviated by the formation of a spur. In an early case he did not appreciate the importance of the spur, and consequently the fæces passed below.

Mr. Barker, of London, said the difficulties of the operation in the groin were nothing compared with those of the lumbar operation, and the dangers were not great with antiseptics. The spur was not always necessary. A case was described in which Mr. Barker had performed the operation mainly for the relief of the pain caused by fæces passing over a diseased rectum. Where the fæces were fluid, it was an advantage to aspirate and thus prevent them from passing over the wound. In one case he thus drew off ten pints.

Mr. Mayo Robson said he was astonished that the difficulty of finding the bowel in cases of lumbar colotomy was not more dwelt on in text-books. The peritoneum was frequently opened, and, he believed, without harm. In case of any difficulty in finding the bowel, his own plan was to open the peritoneum, introduce one finger through the slit in it to find the uncovered portion of bowel, and, having found it, to stitch up the other little

opening. He did not think the inguinal operation was particularly useful in acute obstruction of the bowel, as the bowel was then often much distended by gas or fluid, and where so distended it was difficult to avoid the entrance of its contents into the peritoneum. In chronic cases, however, the inguinal operation offered advantages.

Mr. Laffan referred to a published case of his own.

Sir Spencer Wells spoke of the importance of bearing in mind the distinction between right and left colotomy. In performing left lumbar colotomy we often came down upon a diseased part of bowel. He referred to four cases in which he had performed right lumbar colotomy—or rather made an opening in the cæcum—and all but one did well.

Dr. Ball approved of performing the operation at once—not in two stages—as the mere fact of inserting sutures would produce a certain amount of strangulation which would cause difficulty in the second stage. He had devised a special clamp to hold the intestine to the abdominal walls.

Mr. Allingham agreed that where the gut was much distended, it was advisable to perform the operation in the lumbar region.

Dr. Hector Cameron, of Glasgow, read a paper

ON SUTURE OF THE PATELLA, WITH A NEW SUGGESTION IN REGARD TO DEALING WITH A SHORTENED RECTUS MUSCLE.

He said the necessity for interfering with chronic cases with wide separation of the fragments was admitted. But in recent cases with good fibrous union the need was not so obvious. He justified the operation for recent fractures by the fact that the uniting ligament had a great tendency to lengthen or become ruptured. We rarely got bony union without operation. Two cases were exhibited on whom Dr. Cameron had operated. One was sutured fourteen days, the other fourteen years, after fracture. In the first of these cases he had adopted drainage as Lister did, but in his later cases he had found it unnecessary. In one of the cases he now exhibited, considerable difficulty had been experienced at the time of the operation. The bone was so soft that the holes for the sutures became converted into longitudinal slits.

Mr. Keetley said he had sutured eleven patellæ and two olecranons. Experience had led him to have strong views from what he had seen of patellæ which had been fractured and not sutured. The results of the ordinary treatment for fractures of the patellæ were far less satisfactory than books would lead us to think. Many such cases came for knee-caps to a society to which he was surgeon. He had never seen but one who said he could walk up-stairs easily, and that one he had no opportunity of testing.

Such patients were debarred from work. The dangers of the operation were altogether septic. Antiseptic surgery was not at present fully developed. In two of his cases a bystander came and put his finger (not aseptic) into the wound during the performance of the operation. In every one of his own cases he had found what Macewen had described, viz., the appearance of aponeurosis between the fragments. There was a difficulty in disposing of the wire. In some cases he had had to withdraw it, and others had had to do the same. An American plan, of which he approved, was to dispose of the ends of wire between the fragments. He would operate early and drain the tissues *outside* the joint. He had a strong theoretical objection to shortening the muscle, but had no practical experience of the operation. It was a question of the relative length of the bone and the muscle, and he suggested osteotomy as an alternative.

Professor Thornley Stoker had treated a large number of fractured patellæ, but had never seen such a result as a patient rendered unfit for the duties of active life. In one case a man with two inches separation gained a laborious livelihood as a pedler.

Mr. Foy, of Dublin, spoke of the dangers of the operation. He did not think that osteotomy, as advised by Mr. Keetley, in preference to division of the muscle, would commend itself.

Mr. Mayo Robson said that with the use of antiseptics he had never had any bad results with fractured patellæ. There need be no hesitation in dealing with compound fractures, but as to other cases, he would reserve the operation for old cases in which the limb was useless. He mentioned a case in which the patient broke his patella by falling from a mast. He was operated on, but shortly afterward fell again from the mast. His patella was again fractured, but in a different place.

Mr. Nicholson, of Hull, agreed that ordinary methods should first be tried. If these were insufficient we might then proceed to the more serious operation.

Mr. Barker observed that the operation had not been done in University College Hospital more than once during the last nine or ten years. They could get very good results in other ways.

Mr. Gowans, of South Shields, said he thought the operation was safe and justifiable.

Mr. Thompson, of Curragh, said he always undertook the operation with great precautions.

Dr. Macewen, of Glasgow, said he had cases which had not been operated on, and in which the limbs were most useful.

Dr. Cameron then replied. He said he admitted that good results often followed ordinary treatment, but an immediately excellent result was no argument. Many of the cases on which he had afterward operated had had very good results at first from ordinary treatment.

Dr. Phillippi, of London, then gave a practical demonstration of Professor Unna's method of treating chronic ulcers of the leg.

Friday, August 5th.

Dr. J. K. Barton, of Dublin, read a paper

ON OPERATIVE TREATMENT OF MORBUS COXÆ.

Dr. Barton spoke of the good results following excision of the hip-joint in such cases. In one case he had performed the operation on a patient who was in a very reduced state, and with good results. He maintained that when performed in the final stage of hip-joint disease it could save both life and limb. Shortening of the limb was frequently lessened by the operation, and in some cases by the formation of fibrous bands. Six months after the operation the patient might be restored to perfect health. Two living patients were shown on whom the operation had been performed, and in both there was very fair movement of the joint. In one of the cases there had been disease of the spine, and Pott's curvature was present.

Mr. R. J. Godlee, of London, then read a paper

ON A CASE OF HEPATIC ABSCESS, WITH REMARKS ON STITCHING THE PLEURA.

The abscess was not at first diagnosed as hepatic, owing to its unusual position, and was opened, finally, through the pleural cavity, the two layers of the pleura being stitched together to form a channel for the pus to pass through without entering the general cavity of the pleura. The patient did well. There was slight dulness in the back, but no signs of pneumothorax. A similar case, published by Mr. Knowsley Thornton, was referred to.

Professor Kocher, of Berne, then read a paper on

CACHEXIA STRUMIPRIVA AND MYXŒDEMA.

He had, he said, performed the operation of thyroidectomy in twenty-nine cases, and seen three cases of others. Six patients died, two of them being cases in which the operation had been performed for carcinoma; in one case recurrence took place, in the other it did not. All the six showed signs of cachexia before death. Of those

who lived, twenty showed marked signs of cachexia and six more or less slightly. He concluded that where cachexia had not followed the operation the latter had not been one of total excision. Partial excision was, in his opinion, excellent, but there was no case on record showing that *total* excision was harmless. Within four years fifty-six cases of cachexia strumipriva had been published. We must not forget that the enlargement of the thyroid in goitre was not due to increase of normal gland tissue. He suggested the term cachexia thyroipriva, *i.e.*, by loss of function of the thyroid gland.

Since 1883 observers had come to the following conclusions: (1) that a small part of the gland might do the function of the whole organ; (2) the influence of the thyroid on the blood might be a direct or an indirect one; (3) there was plenty of evidence that the gland was not a blood-forming organ. He referred to the researches of Professor Linski on the examination of lymph from and of blood going to and from the thyroid body.

Mr. Godlee referred to the inquiry now being conducted by the Clinical Society, and said that although the statistics were not yet complete, he believed they would show very few cases of myxœdema following total removal of the gland. Professor Kocher said, that where total removal had been performed, and myxœdema had not followed, accessory parts of the gland had been subsequently found. If myxœdema always followed total removal of the gland, we must discard *total* excision. He asked the plan now practised by Dr. Kocher.

Professor Thornley Stoker described two operations which he had performed in 1882. In one case the gland had reached an enormous size and hung down to the level of the umbilicus. He removed two-thirds of it and subsequently the remaining third. The patient died a week later from pulmonary thrombosis. In the other case he divided the isthmus, and later removed the enormous right lobe together with the isthmus. The patient was now in perfect health, and there was no cachexia. He had no doubt that, as Professor Kocher had said, a piece of the gland was as good as the whole for the performance of its functions.

Mr. Jessop (Leeds) described a case.

Mr. Gowans asked whether Professor Kocher had found cachexia strumipriva and myxœdema identical. Had he found low temperatures in both?

Dr. George Stoker (London) said, that Professor Kocher had set at rest the question of the desirability of removing the thyroid. It was difficult to believe, though, that the thyroid had the elaborate functions attributed to it. He compared it with the spleen, the functions of which were much modified when it was enlarged. Yet the thyroid did not exhibit any change of function even when enlarged to thirty times its normal size.

Professor Kocher replied that the enlargement of the thyroid was not due to hypertrophy of normal gland-tissue. Moreover, in patients with very large goitres we did see an alteration in function, which might be due to the compression of the gland by the abnormal tissue, the normal gland-tissue having almost disappeared. In Switzerland persons with goitre often showed many of the signs of myxœdema. He thought the thyroid was not a blood-forming organ, but one giving off noxious matters from the blood. We might remove one kidney, and it had no effect on the body. So we might remove a part only of the thyroid. Every patient from whom the thyroid was removed had cachexia, except when a small part was left, and then a small goitre came again. He thought division of the isthmus good. His practice was now, in the case of a large goitre causing urgent symptoms, to excise half. The trachea could then go to one side and escape compression. On the other side, if any further operation were necessary, he performed enucleation of the abnormal tissue. It was not so nice an operation as excision, in which there was often but little blood lost. He had found the post-mortem appearances in cases of cachexia strumipriva and myxœdema identical.

Mr. Wheeler then read a paper on

TREPHINING IN MASTOID AND TYMPANIC DISEASE.

He advised trephining on a level with the centre of the external auditory meatus and in front of a line extending to the tip of the mastoid process. Several sections of skulls with the brain *in situ* were exhibited, showing the parts reached by the operation.

Mr. Barker agreed with Mr. Wheeler as to the selection of site, viz., over what had been called the mastoid antrum. He did not agree with the advisability of trephining there for disease of the temporo-sphenoidal lobe, but preferred another site when the bone was healthy.

Dr. Drummond (Newcastle) thought Mr. Wheeler's area not desirable in cases of cerebral abscess. He described a case of the latter. To a patient he had seen several times, with vague ear symptoms and aphasia, he was called in one day suddenly and found him comatose. There was pronounced optic neuritis. He diagnosed cerebral abscess, and as aphasia was the only feature to aid in localization, he suspected pressure on the inferior frontal lobe. The ear disease was on the left side. He suggested trephining over the upper part of the temporo-sphenoidal lobe, about an inch and a half above and slightly behind the meatus. A hypodermic needle introduced through the trephine hole, an inch into the brain, drew off pus. A second opening was made close to Mr. Wheeler's point and no pus found with the needle, so the wound was drained from the first opening. The patient only lived three days, as red softening came on, but speech and consciousness returned. Had the opening been over the mastoid process, it would have been difficult to reach the abscess without penetrating a considerable distance.

Mr. Jessop drew attention to the origin of disease in the mastoid bone, and said it was no use removing the pus unless you could reach the seat of the disease in the bone.

Mr. Pratt said the operation was a favorable one, but trephining the skull in two positions was more serious than doing it in one. If there were disease in the mastoid process, by trephining high up you either left the disease without drain, or had to trephine again. He therefore preferred to trephine over the mastoid, even if a deeper incision had to be made. Being lower down, drainage was also better.

Mr. Walsham then read a paper on

LITHOPLAXY IN MALE CHILDREN.

Several successful cases were referred to, and Mr. Walsham said that to his mind the superiority (for male children) of lithoplaxy over both the supra-pubic operation and lithotomy was established. He had not himself met with a child in whom, after incision of the meatus, a No. 5 or 6 lithotrite could not be passed. Mr. Cadge, however, had met with one. The unusual sensibility of the urethra in children had been much overrated. He had met with children who preferred being sounded without chloroform.

Dr. Ward Cousins (Southsea) agreed as to the suitability of the operation for young children.

Dr. Austin Meldon (Dublin) then read a paper on

THE TREATMENT OF TETANUS.

Dr. Meldon said various methods of treatment had been advised. When he first had a case of acute tetanus he consulted his colleagues, and everyone advised differently from the others. He had collected particulars of nine hundred and thirty-seven cases variously treated. He now urged the value of hyoscyamus, belladonna, and conium given in combination. Under this treatment he had had thirteen recoveries out of seventeen cases. Since the introduction of antiseptics into the Dublin hospitals tetanus had almost disappeared.

Mr. Swan (Dublin) then read a paper on

THE INFLUENCE OF PERIOSTEAL SECTION AND BONE DRAINAGE IN ARRESTING CERTAIN DISEASES OF JOINTS.

The knee-joint was selected as an example, and some cases given. After operation rest was maintained until pain on passive motion had ceased.

Dr. Gibney (New York) remarked that the object was to convert a chronic into an acute disease, and then to treat the same by appropriate means.

Mr. Illingworth then read a paper on

A NEW FORM OF SPLINT FOR THE TREATMENT OF FRACTURES INTO, AND IN THE VICINITY OF, THE ELBOW-JOINT.

The ordinary rectangular splint employed in such cases often led, he said, to deformity, viz., an outward projection of the elbow. By reference to the skeleton, he showed that the arm and forearm naturally formed an angle at the elbow (the latter pointing inward) in the supine position. In pronation of the forearm it was more nearly in a line with the arm. He accordingly suggested that the forearm should be extended and pronated and (the limb being allowed to hang down by the side) straight splints applied. Œdema was prevented by careful bandaging. He had had several successful cases.

Dr. Hall contended that in many cases treated with rectangular splints there was no deformity.

Dr. Ward Cousins read a paper on

TREATMENT OF RETENTION OF URINE BY ASPIRATION THROUGH A CAPILLARY CATHETER.

He exhibited his instrument, which was half catheter, half bougie, the bougie portion being passed in first. It was mainly designed for use in obstinate cases of stricture, and Dr. Cousins said the great secret of success was to distend the urethra well with oil.

Mr. Steele (Clifton) then read a paper on

RADICAL CURE OF VARICOSE VEINS.

The veins which were to be operated on being marked out first on the surface by nitrate of silver, his plan was not simply to divide the vein between two pins, but to cut out a piece altogether. He thought it an advantage to cut in the course of the vein—not across. He had latterly not employed cutting, but seized the vein with torsion-forceps and twisted it till it broke across. It was often, said Mr. Steele, extremely difficult to find the veins when empty. Raising the foot of the bed by two bricks was an aid to after-treatment. His patients had been able to walk about in three weeks.

SECTION IN THERAPEUTICS.

In the Therapeutical Section a paper was read on

THE CLIMATIC TREATMENT OF PHTHISIS-PULMONALIS,

by Professor Charteris, of Glasgow. Professor Charteris said that inquiries should be fairly weighed before deciding on recommending a climatic change to a patient suffering from phthisis. The most important of these was the history of the case and the length of time required for residence abroad. If the history of the case revealed recent and repeated attacks of hæmoptysis, then there was great risk in ordering a removal to a place where the distance is great and where a sea-voyage of any length is necessary. The sea air is markedly exciting to the system, and if sea-sickness also occurs, there is great possibility of hæmorrhage recurring in an aggravated form. The next question is the time necessary for climatic treatment. It should be remembered that one of six months is not sufficient to effect a cure, and that coming back to this country, with its variable and humid atmosphere, is always attended with risk. Two or three years must, as a rule, be spent abroad before a return home can be contemplated with any safety. Moreover there can be little doubt that a permanent residence in the country, where health has been regained, is the best means of obviating relapse. In many European resorts it is out of the question to think of earning a livelihood, *e.g.*, Davos Platz, or the Mediterranean. Fortunately in our colonies places may be found of great benefit to the consumptive, where he may recover and live in health, and be busy. He narrated the case of a patient, aged forty-five, a watchmaker, who crossed to America with him, and who nearly died of hæmoptysis on the voyage. He went on to Colorado, and had been able to start in business there. A young lady, aged nineteen, went to Davos, and remained there a winter. When she returned she was greatly better, but took too much exercise, had a relapse, and died. The great desideratum in consumption was the expansion of the lungs out of doors in pure air. That is just what has been found useful in the ascent at Davos and Malaga, and on board ship. These means practically destroy the far-reaching inference of the bacillus discovery of Koch. No one doubts that Koch's bacilli nestle and multiply on the tubercular bed, but that they originate phthisis, and force the conclusion that tubercles can only come from bacilli, is contrary to the experience and observation of the great majority of the profession. We must believe that phthisis is hereditary, and tends to show itself in the growing maturity of youth, and certain conditions may evoke or originate the disease. We know that some whose means permit of a climatic change, will yet regain health, provided they will discard literary or social pleasures, and spend their lives out of doors. But there are others for whom such prospects can never be. He therefore advocated the formation of convalescent homes where poor consumptives could live in pure air and enjoy the fresh breezes out of towns. In this way their constitution might rally and a cure be effected.

Dr. C. R. Drysdale, of London, read a paper on

THE CLIMATIC TREATMENT OF CONSUMPTION.

The author said that in 1,000 deaths occurring in Paris weekly, 200 were from phthisis and 25 were from external tuberculosis. Dr. Thouvenin has shown that 65 per 1,000 of the deaths among the rich were caused by it, while 230 per 1,000 among the poor succumbed to the disease. Many years ago the celebrated Dr. Stokes had told a friend that in all his experience only two persons had recovered from phthisis, but of late years all who paid much attention to the disease had heard of a great many spontaneous recoveries. He himself had been accustomed to make inquiries at the meetings of the British Medical Association, and he had heard of upward of a hundred medical men who had recovered from the disease. He held that phthisis was a virulent and inoculable disease and, in all probability, the sputum of a consumptive, if subcutaneously inoculated, would produce the disease in a healthy person, as it did in the lower animals. He did not, however, adopt Koch's view that phthisis was often caused by the inhalation of dried sputum. He rather adhered to the view that the bacillus was an external parasite existing in all parts of the world, and chiefly in damp and sunless abodes, and that delicate persons, with or without any hereditary proclivity, inhaled its germs gradually. He doubted whether phthisis was contagious in any way like syphilis or small-pox, for at Davos, where he was last year, it never seemed to spread to the people in the valley, and persons residing in consumptive hospitals were particularly exempt from the disease. With the exception of some able Italian physicians, no one at present seemed to find much use of drugs in the treatment of the disease. They used iodoform as a germicide, and spoke of very good results having been obtained, which he was personally unable to confirm. In the meantime, then, the only chance was hygiene, and climate was *par excellence* the mainstay in

consumption. He had noticed that patients got well in all sorts of circumstances; but certainly suitable climates appeared to aid considerably in effecting a cure. His own estimate of the value of altitude in the treatment of consumption, since he had seen greater good obtained from residence at Davos, or some other "air-cure" in Switzerland or in North or South America than in any other place, although the shores of the Mediterranean and long sea-voyages in comfortable berths in good ships were extremely curative. When he visited Davos, in 1886, he found that the peasantry in the valleys of equal altitude round about the place said distinctly that people did not die of consumption among them; and, naturally, one could not help thinking that this must be due to the absence of germs in the flora of such elevated spots capable of producing the disease. Patients should go to Davos in May, and stay there until they get well, if they can afford it, with occasional trips home in midsummer, and this would cure many. So would a long sea-voyage to New Zealand or Tasmania and back by the Cape, returning by Cape Horn at suitable periods of the year in a roomy sailing-vessel. Those who have to make their living by work should be sent to the Cape of Good Hope, to Colorado, or to the Andes of Peru, which are splendid sanitaria, and where they might work at some trade. In this way many persons might escape from the early death which still falls upon such hosts of young people in all civilized countries.

Dr. Samuel Walker, of Middleboro, said that as Dr. Drysdale had asked to be furnished with the names of medical men who had seen phthisis arrested, he would give the case of a medical student, I. T——, who, at the age of twenty, was found to have phthisis when studying medicine at Edinburgh. He had a cavity at one apex. He lived nearly two years at Davos, with the result that the cavity healed and he was apparently restored to health, and was alive and well.

Dr. Garrett Anderson preferred the climate of the elevated situations of Europe or the continent of America to long sea-voyages, on account of the confined air of the cabins and of the berths.

SECTION IN PUBLIC HEALTH.

In the Public Health Section, Dr. Thorne Thorne in the chair, a paper was read on Friday by the Registrar-General of Ireland, Dr. Grimshaw, on "Class Mortality Statistics."

In the population of Dublin, containing 346,603 persons, a division was made into five classes, as follows: Professional and independent (30,129), middle class (56,781), artisan class and petty shop-keepers (106,142), general service class (147,625), and inmates of workhouses (6,036). The different classes had, first, 2,247 children under five years in the ranks of Class I.; 6,188 in Class II.; 12,895 in Class III.; and 16,111 in Classes IV. and V. This gives the various percentages of children under five years as 7 in I.; 11 in II.; 12 in III.; and 14.5 in IV. and V., thus following the law that the poor are much more prolific than the rich. The death rate for the various classes above cited, is as follows: In Class I. it was 13.4 per 1,000; in Class II., 27.3 per 1,000; in Class III., 22.3 per 1,000; and in Classes IV. and V. it was 33.7 per 1,000.

Dr. C. R. Drysdale, of London, read a paper on

THE INFLUENCE OF EARLY CIRCUMSTANCES ON LONGEVITY.

The author said that Villermé, of Paris, was one of the first to show that comfort prolonged life greatly, by showing that between the ages of forty and fifty years persons in good circumstances, in Paris, had a death-rate of 8.3 per 1,000 against one of 18.7 per 1,000 of persons of similar ages among the poor; and he also found that in Paris, between 1817 and 1836, 1 in 15 of the population of the poor arrondissement died annually, against 1 in 65 in the second, or rich, quarter. Mr. Chadwick had shown that in London there were some sub-districts of the wealthy classes where the death-rate did not exceed 11.3 per 1,000 annually, while there were localities (slums) where it rose to 38 per 1,000. In 1843, when the general London death-rate was 24 per 1,000, that gentleman found, in Bethnal Green, that the mean age at death of the gentry and professionals was forty-four years against twenty-two years among the artisan class; and recently, when the death-rate among the gentry was about 55 in England and Wales, that of the artisan class in Lambeth was 29.5. In 1874, Mr. C. Ansell, of the National Insurance Company, found that only eight per cent. of the children of the upper classes died in their first year, against nineteen per cent. in the general population of Liverpool, and thirty-three per cent. in the slums of that and other large cities. Ansell had concluded that, whereas there died in England and Wales, in 1874, 368,179 persons under the age of sixty years, if the mortality had been equal to that of the rich, only 226,040 would have died, so that poverty in one year had killed 142,139 persons. Dr. Thouvenin had truly remarked that with the exception of cotton-beating, dividing and carding silk cocoons, white lead, and grinding, there are scarcely any trades necessarily dangerous to life; but he found that the deaths from consumption were nearly one-fourth of all deaths among the poor, and only, or about, one-eighteenth of all deaths among the rich. Dr. Edward Smith's statistics at the Brompton Consumption Hospital of London, which he had verified at the North London Consumption Hospital, showed that his patients had been the offspring of parents who, on an average, had produced seven children each, and, as such children were ill-fed, they succumbed more easily to that disease. In the wealthy parishes of Kensington, London, with 186,584 inhabitants, Saint-George, Hanover-Square (88,176), Hampstead (53,758), Saint James, Westminster (28,178), had, in 1886, collectively, 7,779 births, and 5,614 deaths; *i.e.*, a birth-rate of 21.8 and a death-rate of 16 per 1,000; while the poor parishes of Shoreditch (125,508), Bethnal Green (129,895), Whitechapel (68,345), and St. George-in-the-East there was, in 1886, a birth-rate of 38.3 and a death-rate of 24.4 per 1,000. Thus, the poor in London had nearly twice as many children as the rich, and consequently their death-rate was to that of the rich as 3 to 2. The high death-rate of Dublin (26.5) was now explained by Dr. Grimshaw's statistics to be due to poverty, for the richer classes in that city have an annual death-rate of 13.4 per 1,000, against the artisan class, which has 33.7. The percentage of children among the rich in Dublin was seven, and among the poorer classes nearly fifteen, below the age of five years. The low death-rate of the Champs Elysées, at Paris, as compared with the poor twelfth arrondissement, is understood when we know that in the poor quarter children under five years existed to the amount of 957, against 397, in the rich quarter, per 10,000 inhabitants. In 1887, when he, Dr. Drysdale, was vice-president of one of the sections of hygiene at Paris, he found that 100 medical men in Paris produced only 174 children, whereas the average number of children in the poor quarters of Paris in a family, according to M. Haussonville, was 6, and in Paris he had found 7.20. The great economist, Mr J. S. Mill, said that "little improvement could be expected in morality until the producing of large families was regarded in the same light as drunkenness," and all enlightened hygienists would re-echo that sentiment. For his, Dr. Drysdale's, part, he was convinced that the health of the poorest classes would never be satisfactory until they were prevented, by public opinion, or, better still, by statute law of some kind, from engendering such enormous and unfortunate families. And if he was right in this opinion, what would the Section say to the conduct of the Fellows of the Royal College of Physicians of Edinburgh, who, in February

last, had threatened one of their members, Dr. Henry A. Allbutt, of Leeds, with expulsion from the list of members of the college, because he had explained, in a sixpenny pamphlet to the poor, the simple and harmless methods, now known to all enlightened citizens, whereby they might restrain the number of their children within the powers of their industry to rear them? It was a disgrace to a body of educated men to be so silly and so inhuman, and he sincerely trusted that they had already repented, and would ask the pardon of Dr. Allbutt.

In the discussion which followed the reading of these papers, Dr. Tatham (Salford) said he had no means in Salford of testing Dr. Grimshaw's statistics; but he had divided the population according to the class of houses they inhabited, and his figures tallied well with those of Dr. Grimshaw. One fact astonished him in Salford, and that was that there seemed to be seven times as many cases of scarlet fever among the poor as among the rich in that town. Dr. Grimshaw had grouped several years together in this first attempt; but after this he would give the yearly averages, which would be most useful. In England such a plan was not yet in vogue; but then Dr. Grimshaw was a physician, while the English Registrar General was only a layman.

Dr. Thorne Thorne asked whether the new statistics would keep up the enumeration of trades.

Dr. Grimshaw said that there still existed a house classification; but there were many so-called first-class houses let out in tenements with fourth-class accommodations. Dr. William Fare was the great founder of vital statistics in England. The classification by trades was not interfered with.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 2 to October 15, 1887.

Hall, William R., Captain and Assistant Surgeon. Ordered from Davids Island, to Fort Custer, Mon. Ter. S. O. 232, A. G. O., October 5, 1887.

Price, C. E., Captain and Assistant Surgeon. Ordered from Fort Custer, to Fort Du Chesne, Utah Ter. S. O. 232, A. G. O., October 5, 1887.

Suter, William N., First Lieutenant and Assistant Surgeon. Ordered from Washington Barracks, to Fort McKinney, Wyo. Ter. S. O. 232, A. G. O., October 5, 1887.

Weisel, D., Captain and Assistant Surgeon. Ordered from Fort McKinney, to Fort Sill, Ind. Ter. S. O. 232, A. G. O., October 5, 1887.

Horton, S. M., Major and Surgeon. Ordered from Fort Riley, to Fort Adams, R. I. S. O. 232, A. G. O., October 5, 1887.

Bache, D., Major and Surgeon. Ordered from Fort Adams, to Fort Riley, Kansas. S. O. 232, A. G. O., October 5, 1887.

Kimball, J. P., Major and Surgeon. Ordered from West Point, to Fort Elliott, Texas. S. O. 232, A. G. O., October 5, 1887.

Newton, R. C., Captain and Assistant Surgeon. Ordered from Fort Elliott, to Davids Island, N. Y. Harbor. S. O. 232, A. G. O., October 5, 1887.

Heizmann, C. L., Major and Surgeon. Ordered from Fort Ontario, to West Point, N. Y. S. O. 232, A. G. O., October 5, 1887.

Carter, E. C., Captain and Assistant Surgeon. Leave of absence further extended fifteen days. S. O. 231, A. G. O., October 4, 1887.

Cabell, J. M., First Lieutenant and Assistant Surgeon. Relieved from further duty in connection with the competition of "Team of Distinguished Marksmen," at Bellevue Rifle Range, to take effect October 1st, and will return to his station, Fort Omaha, Nebraska. S. O. 95, Department of the Platte, September 27, 1887.

Cabell, J. M., First Lieutenant and Assistant Surgeon. Will be relieved from duty at Fort Omaha. Assigned to temporary duty with Battalion, Sixth Infantry, in the field. S. O. 98, Department of the Platte, October 1, 1887.

Border, W. C., First Lieutenant and Assistant Surgeon. Will be relieved by officer commanding troops, upon arrival of Assistant Surgeon Cabell, and will return to his station at Fort Douglass, Utah. S. O. 98, Department of the Platte, October 1, 1887.

Alexander, Charles T., Lieutenant-Colonel and Surgeon. Relieved from duty as attending surgeon and examiner of Recruits at St. Louis, Mo., and ordered for duty at Fort Meade, Dakota Ter. S. O. 235, A. G. O., October 8, 1887.

Cunningham, T. A., Captain and Assistant Surgeon. Died October 12, 1887, at Fort Lewis, Colorado.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 8, 1887.

Martin, William, Assistant Surgeon. Detached from Hospital, Norfolk, and granted sixty days leave.

Bates, N. L., Medical Inspector. Detached from Naval Dispensary, and ordered to Examining and Retiring Boards.

Price, A. F., Surgeon. Ordered to the Naval Dispensary, Washington, D. C.

Waggener, J. R., Surgeon. Ordered to the Receiving Ship, Minnesota.

Fitzsimmons, Paul, Surgeon. Detached from the Minnesota, and ordered to the Morion, October 15th.

Atler, Louis W., Assistant Surgeon. Detached from the Receiving Ship, Vermont, and ordered to the Morion, October 15th.

Rush, W. H., Passed Assistant Surgeon. Detached from the Coast Survey Steamer, Blake, and ordered to the Navy Yard, New York.

Berryhill, T. A., Assistant Surgeon. Detached from the Minnesota, and ordered to the Blake.

Drennan, M. C., Surgeon. Detached from Naval Academy, and wait orders.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 15, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	51	7
Scarlet fever	61	9
Cerebro-spinal meningitis	6	5
Measles	18	0
Diphtheria	96	31
Small-pox	1	0
Yellow fever	0	0
Cholera	0	0

The Fate of Extravasated Blood.—The object of a recent research by Dr. William Hunter was primarily to determine the share taken by the liver, the spleen, and the bone marrow in the disposal of extravasated blood (*British Medical Journal*). The method of research was the transfusion of large quantities of blood into the peritoneal cavity, the blood being in all cases derived from an animal of the same species. The animals used

were the rabbit and dog. I. Local Fate.—1. The part taken by cells in the local changes going on around extravasated blood is of the greatest importance; the cells being of two kinds—those of leucocyte, and those of connective-tissue origin. 2. The formation of blood-pigment from the red blood-corpuscles is mainly a "cellular" process, being effected through the agency of cells, either by enclosure of the corpuscles bodily within them, or by disintegration of the red corpuscles and then enclosure of their fragments. 3. In the process of so-called "organization" of blood-clot both varieties of cells play an important part; but while both leucocytes and connective-tissue cells are concerned in the disintegration of red corpuscles, the former, in addition, effecting the removal of the *débris* from the seat of extravasation, the connective-tissue cells alone are concerned in the process of formation of fibrous tissue by which ultimately the clot becomes replaced. II. Absorption.—4. The absorption of extravasated blood applies not only to the serum of the blood, but also to the great majority of the red corpuscles which remain unentangled amidst coagula or the surrounding tissues. 5. This absorption is extremely rapid, both from the subcutaneous tissues, but especially from the larger serous cavities. 6. In the case of the peritoneal cavity the absorption of the serum and red blood-corpuscles is effected almost entirely through the lymphatics of the diaphragm. 7. Under such circumstances the increase in the number of corpuscles within the circulation is observable one hour after injection, and steadily rises till it reaches a maximum about the second or third day, the time varying according to the quantity injected. 8. Extravasation *per se* does not affect the vitality of the red blood-corpuscles; if absorbed back into the circulation within a day or two, they continue to live as before. 9. Their longest duration of life under such circumstances (in the rabbit) varies from two to four weeks, this duration applying naturally to only a few of them. 10. The probable life-duration of the red blood-corpuscle in man is about three weeks. III. Ultimate Fate of the Absorbed Corpuscles.—11. The three great seats of blood destruction within the body, under pathological as under physiological conditions, are the liver, the spleen, and the bone marrow. 12. The nature of the process of destruction in the liver differs essentially from that in the spleen and bone marrow. 13. In the latter the process of blood destruction is mainly a cellular one, comparable in all respects with, although much more rapid and complete than, the similar processes taking place locally at the seat of extravasation; in the former the destruction is much more rapid than in the spleen and bone marrow. 14. After increased destruction of blood-corpuscles within the body the local evidences obtainable are, in the case of the liver, increased richness of its substance in iron, and the presence of granules containing free iron within the liver-cells; in the case of the spleen and bone marrow, increase in the amount of pigment containing free iron found within these organs. 15. In health a definite relation is maintained between the amount of blood destruction which takes place in the liver on the one hand, and in the spleen and bone marrow on the other. 16. Any disturbance of this relation on the part of the liver is of much greater consequence than on the part of the spleen or bone marrow. 17. The former is, in all probability, the pathological change which lies at the root of progressive pernicious anæmia, as the latter is the probable cause of the anæmia of leucocythæmia. 18. The rapidity with which blood-corpuscles introduced into the circulation become destroyed is very great, a number equivalent to about four or five per cent. of the animal's own blood being destroyed daily. 19. The small quantity of blood transfusible into the organism in the case of man is therefore entirely removed from the body in a few days at most, probably not longer than three or four. 20. Transfusion of blood in the human subject in cases of pernicious anæmia, with the object of increasing the number of corpuscles, is devoid of all physiological basis, and is simply adding fuel to the flame, since the fault in this disease is not one of defective formation of blood-corpuscles, but one of excessive destruction of those already present.

The Practice of Medicine on the West Coast of Africa.—Dr. Ralph St. J. Perry, of Indianapolis, sends us an interesting account of his experience as a medical missionary in Liberia, which was not of a nature to incite to a wholesale emigration of ambitious young physicians to that land. Dr. Perry writes: "My first hint to one intending to resort to a semi-civilized tropical country would be: Don't go; you will find the United States a much pleasanter, healthier, and safer country for you. That is why I came home. If you go, make a special study of the diseases and surgery of the country and take an outfit suited accordingly. Take plenty of drugs, as you cannot buy them when away from America or Europe; your surgical outfit should be full and of the best make. Three-fourths of your work will be surgical, and the man with the best tools usually gets the most work. All instruments, whether nickelled, gold- or silver-plated, or made of pure silver, must be kept anointed with vaseline, and cleaned every week whether used or not, otherwise they will become rusted and clogged with dirt or insects. Perishable goods, as silk catheters, bougies, and like instruments, must be kept in air-tight tin cases; the ants will destroy them if they are exposed, for the white ants of the tropics are terrors. Keep all your instruments under lock and key; the native of the tropics loves a pretty knife, and will appropriate one, or anything else, should the opportunity offer. In general practice you will have very little to do; the people will look upon you as a foreigner who knows little or nothing of the local fevers and other diseases, and they will trot off to some native medicine-man and take his "bush herbs," teas, and other de- and con-coctions. It will be well for the physician to look up the native remedies of his new location. If the place is of any commercial importance he will have some practice among the foreign population, and if he is able to rattle off a mass of information about the native remedies, he need not fear native competition. Beyond several cases of apoplexy and constipation, I encountered no medical work. Only one obstetrical case came to me—one in which instrumental assistance was thought necessary. I proposed forceps, but objection was made; a native obstetrician arrived, greased his hands, squatted between the woman's thighs, braced his heels against her buttocks, slipped both hands up into the vagina, gripped the head, and with a steady pull soon brought it to view. For this service he received one chicken and a pint of rice. Gynecology is practically an unknown science in Africa, because of the absence of such diseases, and of religious prejudices and ignorance. Skin diseases of every class are abundant; not only do you meet the purely tropical diseases, but also those of the temperate zone much aggravated. Leprosy, elephantiasis, molluscum, yaws, and numerous others as interesting, are met with daily. Plenty of opportunity is offered for study in this line. Venereal diseases are of frequent occurrence. During ten months' active practice in Liberia, covering a territory of six thousand square miles, inhabited by ten million people, I never saw a case of bubo, chancre, chancroid, or advanced syphilis. However, gonorrhœal pus flowed freely from about one man in every twenty-five, stricture occurred in about one in fifty men, and hydrocele in one in ten. The women, from some unknown cause, seemed much freer from venereal troubles than the men. Tubercular disease of the testicles is common, but the men decline to have it treated. I found that men would much rather suffer from a disease of the testicles than to have them removed. Being Mohammedans, they adhere strictly to the law as laid down in Deuteronomy—that no one injured in his privy parts shall enter the temple of the Lord. As I remarked before, three-fourths of your work

will be surgical, you will find the people ignorant, and they will leave everything to your judgment; you will have no one to consult with, and you will have to depend upon yourself; it is good training for a young man. Many severe cases of ulceration, gangrene, elephantiasis, and other diseases demanding amputation, will come to you and you will have to do the work without trained assistants. Herniæ will cross your path often, and I would advise you to operate for a cure whenever possible, as a reliable truss is hard to get, unless you are mechanic enough to make one yourself. Umbilical hernia will often be found in children, and in men who have strained themselves, but it is not looked upon as anything dangerous. Since my experience with dozens of these cases I am inclined to look upon umbilical hernia as something the danger of which is greatly exaggerated. Much trouble may be experienced in the use of ether and chloroform, the natives refusing to take it, they believing that a person under ether is dead, but is afterward resurrected. I have performed many severe operations without an anæsthetic, solely on account of this superstition. Drugs and chemicals should always be packed in impervious tin or glass containers, as the dampness of the tropics, coupled with the ravages of insects, will destroy most anything. Above all, look out for your own physical welfare; it will be necessary for you to become acclimated, and not a few succumb while going through their first fever. Take a supply of remedies for your personal use, and *use them* upon the slightest provocation. Dress warmly; don't think that because you are in a torrid climate you can go half naked. Bathe night and morning, and eat fresh food; canned goods cause more deaths in the tropics than anything else. Don't be ashamed to come home if you get sick. I would rather be ridiculed as a live man than mourned for as a corpse. Another point: don't have a wife to accompany you in your venture; Northern women do not bear pregnancy well in the tropics, and I would suggest that you wait until you see whether you can stand the climate yourself before exposing a more delicate constitution to the strain. Subscribe for two or three good medical journals and see that you get them—the mail agents often throw papers away as unworthy of carriage. As a rule, very few physicians in the tropics take any medical journals, and if you keep up with the times you can get ahead of your competitors. A pharmaceutical journal will materially assist you in purchasing supplies, and will keep you informed concerning new remedies."

Cataract Operations without Iridectomy.—On this point, now much discussed by ophthalmologists, Dr. Frank T. Smith says (*American Journal of Ophthalmology*): "In looking over the whole subject, it would seem that there is a wide difference of opinion in reference to the relative value of the different operations. It is generally conceded that to operate with an iridectomy is as safe as any method that has been suggested. The various other operations are still on trial. It will take some time to determine their value. One would naturally think that Von Graefe and other eminent ophthalmologists knew what they were about, when they abandoned the method without an iridectomy. The main objection to the latter operation is the tendency to iritis after the operation. This has been reported by most observers. With this is the danger of adhesions to the capsule. There is also danger of prolapse of the iris. This has occurred in some cases several days after the operation. The method that gives the best average results is the one that commends itself to conservative surgeons, not the one that is the most brilliant in a minority, or even in a majority, of cases. If in a minority, the effects are below the average by the other method. It is better that ninety-five per cent. should be able to see to get about than that seventy-five per cent. should be able to read the finest print, and twenty per cent. not be able to find their way. Judged on these principles, the von Graefe method seems to hold its place as the standard operation. By this method the best operators lost two or three per cent. by suppurative processes. It can hardly be expected that these results can be excelled. If they can be equalled by any method that leaves the iris intact, it will be an improvement.

Is there Want of Progress in the Healing Art?—Every now and then the old question is revived, "Are we better than our fathers?" This is particularly true in regard to the practice of medicine. The latest revival is furnished by Professor Gairdner, in his recent address on medicine, delivered at the Dublin meeting of the British Medical Society. He says that undoubtedly there are some points of detail which have not varied, for which even modern physicians are indebted to the sagacity and foresight of the ancients (*The Lancet*). But have we departed from the tradition of their work? Are we really so much in advance as we boast ourselves? In other words, Has medicine yet emerged from empiricism? Has it ceased to pin its faith to vague theories? Is it, as Professor Gairdner puts it, really more *stable* than it was a century ago? This, after all, is the real test of advance in the healing art; and, tried by these questions, there are, it must be confessed, many signs of absolute want of progress. In truth, there is no physician who will not confess that, in spite of the very notable achievements in the building up of the science of medicine, and in basing our practice upon the firm foundation of observed facts, there are yet wide regions in which we are still groping in the darkness, where we rely upon the "art" that clings to us from the past. It is slow and weary work, this casting off of old traditions and searching for the surer ground of fact; but it is being done, and that with increasing energy and hope. Professor Gairdner, in his calm and impartial survey, showed us what comfort we may glean from such reflections, and we may confidently look forward to a time when rational medicine will prevail; this, too, in spite of the many disheartening indications we see around us of the spread of quackery among the public. For it is not only the medical man who has to be imbued with the new spirit; his patients also sadly need enlightening upon the subject. The old faith in medicine as a mysterious and well-nigh miraculous power has not yet died out, and it is fostered by the unscrupulous, who trade on ignorance and folly. But how is it with ourselves—we the legitimate heirs of Hippocratic medicine? Are we really worthy of the laudation we are so apt to indulge in, and have we wholly thrown off the shackles of tradition? It seems to us that Professor Gairdner supplied an answer to this question, and, indeed, the only possible answer. He showed that, strictly speaking, we have no data of comparison between the medical practice of our day and that of Hippocrates or Galen. We have their dicta and their principles, but we have no clinical records sufficiently detailed to contrast the efficacy of their methods with that of our own. No one can deny the great service rendered by "the Æsculapian priest who first emancipated the art of medicine from the trammels of priestly control on the one hand, and of philosophic dogmatism on the other," and, wide as is the interval between his days and ours, there is still much in the Hippocratic tradition that remains unshaken. Contrasting earlier times with the present, Gairdner sought for evidence of a greater stability in medical doctrine now than then. He surveyed the field of modern medicine, and showed that in some respects, especially in the overwhelming rush after new remedies, we have not much to boast of. There is no gainsaying that in some directions medicine has attained as great a stability as it is possible to conceive, but the problems are so vast and numerous that we cannot marvel at the uncertainty in which we often still remain. Happily, however, we are no longer dominated by any theoretical system of universal application,

and we are daily striving to rid ourselves of all that is empirical in practice. We have this advantage over the time of Cullen, that we are learning more of the nature of disease and of the action of remedies than was known to him, and our practice is becoming simpler and sounder in proportion as that knowledge widens. Among the hopeful signs of an increasing stability in medicine, Professor Gairdner adduced the advance of sanitation, the recognition of the self-healing powers in acute disease, the banishment of venesection (or rather its rational restriction) as a remedial measure, and the more enlightened practice of feeding the fever patient rather than bleeding or overstimulating him. These are, indeed, great signs of progress, and separate us from the practice in vogue long after Cullen's day by an immeasurable distance. Up to that time it might have been questioned whether Sir William Hamilton's query, whether the practice of medicine had made any advance since the days of Hippocrates, was not justified, but no one dare assert it now. The Hippocratic tradition has been broken in its strongest link. Professor Gairdner himself has been the witness of this revolution, and has taken no small part in furthering it. There is no doubt that in these respects at least we have gained wisdom, and it has come to us not through the adoption of any theory or as a revulsion from "orthodox" practice, but as the outcome of that patient investigation of natural phenomena of the healthy and diseased body and its environment which forms the basis of scientific medicine. That the gain is a substantial one is to be seen in the instance, cited by Professor Gairdner, of the treatment of fevers; for although the precise value of antipyretic methods is not fully proved, there can be no question of the gain derived from the change from lowering to restorative methods, and the substitution of easily-assimilated food for excessive doses of alcohol. There still remain many branches of medicine in which art lags behind science, and there are prejudices and traditions, both among the laity and the profession, to be eradicated before we can be satisfied with real progress.

Neuralgic Headaches with Apparitions of Unusual Character.—Dr. S. Weir Mitchell reports in *The American Journal of the Medical Sciences*, five peculiar cases of migraine which must be very rare, since with his large opportunities he has seen but four examples. In the cases he describes the ordinary subjective images of zigzag lines or rotating wheels were replaced by more definite shapes, so as sometimes to induce the belief for a time, on the part of the patient, that a ghost had been seen. In two cases the vision came as the only visual phenomenon of severe headaches. Now and then the apparitions were various, at times followed the common zigzags, and at others occurred in the intervals between a succession of exasperating headaches.

The Mental Differences between Men and Women.—Our social system hinges so much upon the relative interests, claims, and capacities of men and women that too much assiduity cannot be employed in endeavoring to mould public opinion upon a question whose issues are so vital and far-reaching. The Mahommetan regards woman as probably soulless. Needless to add, he makes her a slave. The modern movement for promoting the higher education of women would have been impracticable but for the steady growth in the public mind of a conviction that this enlarged culture was not only feasible but an obvious duty. The miserable travesty of education which was formerly thought good enough for young women—the scraps of history and mythology, the music, dancing, and deportment, so long the staple pabulum at "finishing" schools for young ladies—could have been tolerated only by a generation which had accepted without question or examination the low views of female intellectual power prevailing in a former epoch. Hence, such questions as those handled so ably by Mr. Romanes, in his paper recently published in the *Nineteenth Century*, are no mere academic discussions, but problems pregnant with conclusions of immense practical importance. Mr. Romanes cannot be reckoned as a partisan of either side. He sums up, as he himself admits, "with almost brutal frankness," the various intellectual deficiencies of women, real or supposed, but adds that "these elements of weakness are in chief part due to women as a class not having hitherto enjoyed the same educational advantages as men." We are glad of this admission, which has a very vital bearing upon current controversies. The opponents of the higher education of women are singularly unfortunate in their line of argument when they dwell with apparent satisfaction upon the superiority of men in depth of insight, comprehensiveness of view, originality, creative faculty, and judgment. Granted that in these respects women are, as a class, somewhat inferior to men, the legitimate deduction is not that feminine culture is useless or futile, but rather that it should be encouraged by every means in our power, in order that women may, as soon as possible, make up the lee-way consequent upon centuries of apathy and of neglect of their intellectual claims. We are somewhat surprised that Mr. Romanes should attach such paramount importance to the fact of the female brain weighing on the average about five ounces (one-tenth of the whole) less than the male. We are hardly prepared to admit either of the premises upon which an argument can be founded for regarding this deficiency as a necessary sign of intellectual inferiority. These premises are, first, that size of brain is a fair gauge of mental power; and, secondly, that the difference of size between the brains of men and women is greater than might be expected from the difference between their bodies. As regards the first point, cerebral physiology is still in too nebulous a condition to enable us to say more than that, as a general rule, idiots have small brains and men of distinguished capacity large brains. When we put aside the *monstra*, either of excess or defect, it is by no means clear that the possession of a few ounces of brain-matter above the average is a fair gauge of intellectual pre-eminence. Further, the remarkable conclusions of Ferrier and his school have established a surprising closeness of relation between the brain-substance and the muscular system, while they have shed very little light upon the *nexus* between cerebral matter and intellect. It is a very fair question for investigation whether the smaller brain of the woman is not in large part due to her comparative muscular inactivity. As regards the second point, namely, whether the smaller brain of the woman is not simply part and parcel of her smaller body, we are by no means satisfied with Mr. Romanes' rather dogmatic statement that the deficiency of five ounces is "proportionally a greater difference between the male and the female organisms, as a whole." It is a very open question whether the body weight of the average man does not exceed that of the average woman by fully one-tenth. The progress of female education during the brief period in which it has been intelligently and thoroughly cultivated is surely very striking. Women are everywhere justifying the hopes of their champions, and disappointing the gloomy vaticinations of their opponents. Their university successes have exceeded the most sanguine anticipations, and such a brilliant achievement as that of Miss Ramsey, at Cambridge, this year, is enough to cause grave questionings to believers in the natural and inherent intellectual inferiority of women. While we thus take exception to some of Mr. Romanes' lines of argument, we are thoroughly with him in his condemnation of the fatuous notion of some feather brained reformers that there is no such thing as sex in mind; and that, granted an identity of training and environment, men and women would be in all respects mentally alike. We cannot give space to discuss this theory, and must rest content with the statement that biology and psychology alike emphatically repudiate it. We doubt whether woman is necessarily and essentially inferior

mentally to man; we are quite sure she is mentally dissimilar. The great maternal function alone could not operate without gradually inducing intellectual differences which are perpetuated by sexual transmission. All experience tends to show that woman shines in intuition, man in judgment; that woman is strongest when impelled by emotion, man, when impelled by will; that man is creative, woman administrative; that woman is greatest in self-sacrifice, man in conquest and achievement. Be these differences inherent in sex, or the outcome of evolution, their existence can hardly escape any observer who does not start with some preconceived theory.—*The British Medical Journal.*

"Stooping Forward."—Everyone knows that stooping forward, particularly after rising quickly from bed in the morning, when the stomach is empty and the heart has less than ordinary support from the viscera below the diaphragm, is very apt to occasion a form of faintness with vertigo not unlike that which occurs in seasickness. We do not at the moment speak of the faintness and giddiness from cerebral anæmia, which are directly consequent upon suddenly assuming the erect, after long continuing in the recumbent, posture; but of the more alarming sensation of being in the centre of objects which are rapidly passing away, usually from left to right, with loss of power to stand or even sit, and an almost "nightmare" feeling of inability to call for help or do anything to avert a catastrophe, while throughout the experience the sufferer retains painfully acute consciousness. This, we say, is familiar as one at least of the effects not uncommonly produced by stooping forward under the special conditions indicated. With many other varieties of the vertigo consequent upon heart weakness or cerebral anæmia observation or experience has made us all acquainted. We cannot, however, help thinking that the consequences of even partial compression of the veins of the neck, offering an obstacle to the return of blood from the head, with its important organs, are not so well recognized. The peculiar form—or, more accurately, the several forms—of headache distinctly caused in this way when the head is long bowed forward on the chest, bending the neck on itself, cannot fail to occur to everyone; nor will the high tension of the eyeball, the turgid and heavy eyelids, the snuffling nose, the deafness, with buzzing or throbbing in the ears, the heavy breathing, and the puffed and perhaps flushed or darkened color of the face, resulting from the obstructed venous circulation through the bended neck, be forgotten. There are other and more perilous, though secondary, effects of leaning forward when the heart is weak, or the blood-vessels are not so strong as they ought to be, which should not be overlooked. Beyond question the extra strain thrown upon the apparatus of the circulation by anything that impedes the free passage of blood through almost any part of the venous system is more severe and dangerous than a *physically* equal strain thrown on the arteries. At least this is so in adult life, and, without going further into details in connection with the *modus operandi* of the mischief to which we point, it may be permissible to urge that the subject is one to which attention may be usefully directed. The weakly, and those who are not unlikely to have hearts readily overburdened, and blood-vessels easily stretched beyond recovery, or even ruptured, should be warned quite as earnestly against suddenly assuming, or too long retaining, postures which do—however slightly and partially—impede the return of blood through the veins. We know how prolonged sitting may cause the veins of the legs to become distended, and either give way or permit the extravasation of their contents. When this sort of thing happens, even though in comparatively trifling degree, in the case of vessels directly connected with such delicate organs as the eye, the ear, and the brain, it is easy to see that the results may be very serious in their character: and probably few postures commonly taken up by persons who lead somewhat sedentary lives are so prone to do mischief unnoticed as that of "leaning forward," as at work at a table which is not sufficiently high to insure the head being so raised that the veins of the neck may not be in any way compressed, or the return of blood from the head embarrassed or delayed. We see reason to believe that if this apparently small matter were more generally understood there would be fewer head and heart troubles, and we will go so far as to say that some lives now lost would be saved.—*The Lancet.*

Membranous Enteritis Followed by Intestinal Perforation from Ulcus Rotundum.—Dr. Rothmann has described the case of a patient with intestinal perforation, who during life had passed those fibrinous masses usually described as characterizing membranous enteritis. The patient, who had been under observation for several years, suffered from intestinal obstruction, and had had for nine years bleeding hemorrhoids, for which he had been successfully operated upon. Soon after this, he was attacked with colicky pains accompanied with vomiting. He complained of pain in the left hypochondrium. The heart showed nothing abnormal. The pain passed off with a sensation as if fluids and gases were passing through a constricted spot in the intestines. At the same time with such sensations fibrinous masses always appeared in the dejections. Two years before, for the first time, there appeared evacuations of dark blood, which ceased after the use of ice and acetate of lead. After a considerable time they ceased, and appeared for the last time in January of the present year. The patient then rallied and looked well. No tumor was to be felt in the abdomen. On the night of June 16th, he was suddenly seized with the severest pain, became very pale and had a small and quick pulse. For the first time vomiting of blood occurred. The abdomen was hard as a board. There was a smothering sensation referred to the sides and the lower abdomen. The symptoms were clearly those of intestinal perforation. Operation was out of the question on account of the marked collapse. Death occurred in twenty hours. Post-mortem section showed a round ulcer of the duodenum, and rupture *in loco*, adhesion to the colon at the lower part of the ulcer, while the tear took place at the upper part of it. In the colon was a slight stenosis which evidently corresponded to the place the patient had described as feeling narrowed. There was no other lesion in the colon.—*Boston Medical and Surgical Journal.*

The methods of some of the "Christian Scientists" are thus depicted by a lady patient of mine who was beguiled into a séance: After I was seated opposite the faith-healer, she asked: "Do you believe on the Lord Jesus Christ?" "Oh, yes." "Well he can relieve you!" Then putting her hand over her eyes she sat for about fifteen minutes repeating rapidly in a low voice: "Jesus Christ, Jesus Christ, Jesus Christ, Jesus Christ, Jesus Christ, Jesus Christ, Jesus Christ—two dollars, please." And I paid it willingly, thinking I had learned what a fool I was very cheaply.—*Kansas City Medical Index.*

Iodoform.—Dr. John A. Wyeth, of N. Y., writes: "In regard to your editorial in the Record of October 1st, reviewing the various contributions to surgical literature, on the aseptic and antiseptic properties of iodoform, I beg to differ with one of your conclusions, namely that "practical surgical experience continues to favor it."

For two years past I have abandoned it in dressings, and have never had better results—I am forced to conclude that it is an unnecessary complication the to aseptic dressings, to say nothing of its persistent and offensive odor. The employment of the weaker sublimate solutions for irrigation 1 to 3000, and 1 to 5000, the sublimate gauze dressings applied moist and kept so by protective will secure in my opinion as perfect asispsis as is possible.

FIFTY CASES OF CROUP IN PRIVATE PRACTICE TREATED BY INTUBATION OF THE LARYNX, WITH A DESCRIPTION OF THE METHOD AND OF THE DANGERS INCIDENT THERETO.

BY JOSEPH O'DWYER, M.D.,

VISITING PHYSICIAN TO THE NEW YORK FOUNDLING ASYLUM.

IN estimating the value of any method in the treatment of disease, we are compelled to rely chiefly upon statistics, unsatisfactory though they often may be. A plausible theory is very seductive, but it will not cure disease. Theories, indeed, may and often do lead up to the adoption of certain methods of treatment, but there their office ends, and henceforth the therapeutic measures based upon them must be judged by a comparison of their results with those of the older established methods.

These are the considerations which have led me to prepare the following table, giving a summary of the results obtained in my first fifty cases of intubation of the larynx in private practice.

Prior to the time covered by this report, that is from Jan., 1880, to Dec., 1885, or during the experimental stage of intubation, I operated on sixty-five cases of croup, sixty of them being in the New York Foundling Asylum, and had but nine recoveries, or not quite 14 per cent.

I have never resorted to intubation until the symptoms of laryngeal obstruction were so urgent as to plainly indicate impending suffocation, unless the child were relieved by operation. These symptoms were marked recession of the supra-clavicular and episternal regions, restlessness and absence of respiratory murmur over the lower posterior portion of the lungs. Persistent cyanosis was also present in many of the cases, but this comes too late, and is too uncertain a symptom to wait for. Some cases of croup die without any marked cyanosis, and others, in whom this evidence of toxæmia has existed for some time, do not rally even after the dyspnœa has been relieved. Temporary cyanosis, which subsides with the disappearance of the glottic spasm which produces it, is of no special significance.

During the period of time covered by these statistics (from December, 1885, to December, 1886) I was called upon to operate in four additional cases of undoubted diphtheritic croup, but did not consider the symptoms urgent enough to demand interference. They all recovered without operation. In two instances I was sent for a second time, which is an evidence that the attending physicians regarded the symptoms as sufficiently grave to call for interference. I mention these cases particularly to direct attention to the advantage from a statistical point of view of early operation, whether intubation or tracheotomy, and to emphasize the fact that the cases embraced in the following table were desperate ones, and such as, in my opinion and in that of the attending physicians, would have died of suffocation, unless relief to the laryngeal stenosis had been afforded. Out of the 24 cases from which the urine was obtained for examination, albumen was found in 19 of them. The cause of death was due in 18 cases to extension of membrane to the bronchi, in 5 cases to exhaustion, in 5 cases to nephritic complication, in 4 cases to pneumonia, in 3 cases to sepsis, in 1 case to œdema of the lungs, in 2 cases not stated, as they were not seen after operation. Total, 38 cases. In the twelve cases that recovered, the tube was retained on an average of 5 days and 7 hours. The 38 cases that died, lived on an average of 2 days and 7 hours after intubation. The duration of the laryngeal symptoms before intubation averaged 3 days and 6 hours in those that recovered, and 2 days and 6 hours in those that died.

No autopsies were obtained, and it is quite probable that broncho-pneumonia, not revealed by the physical signs, existed in a much larger number than given above.

Method of practising intubation of the larynx.—A set of intubation instruments consists of five tubes[1] of different sizes, an introducer, an extractor, a mouth gag, and a scale of years. Each tube is supplied with a separate obturator which serves the double purpose of attachment to the introducer, and of filling the lower extremity, and rounding it off into a probe-point, so as to prevent injury to the tissues, and scraping off of membrane while the tube is being inserted. The numbers on the scale represent years. The smallest tube, when applied to the scale, will reach the first line marked 1, and is suitable for children of one year old and under. I have occasionally used this size in children of two years of age, but, while there is no danger of its slipping into the trachea, it is very liable to be coughed out. The second size will reach the line marked 2, and is intended for children between one and two years of age. The third size, marked 3–4 on the scale, should be used between two and four years. The fourth size is for the next three years, and the largest is for children from eight to twelve years of age, who have not yet reached puberty. If used in older children, a string should be left attached and passed around the ear, to obviate the danger of its slipping through into the trachea, owing to the rapid increase in the size of the larynx, which takes place at the age of puberty.

In selecting the tube to be used, some allowance should be made for the fact that the male larynx in children, as in adults, is larger than the female. Also for the size of the child compared with its age. A small delicate girl of three and one-half years might require only a two year size, while a large boy of the same age will sometimes require the five to seven size.

After selecting the proper tube, a thread about eighteen inches long, preferably of braided silk and not too thick to wedge the obturator too tightly in the tube, nor so fine that it will cut or break, is passed through the small hole near the anterior angle, and the ends tied to prevent its being accidentally pulled out, either in removing the instrument from the mouth, or by the patient getting the hands free and seizing one end of it. The obturator is now screwed tightly to the introducer, to prevent its rotating while being inserted, which would be liable to bring the posterior projecting portion of the flange under the epiglottis. When the tube is attached to the introducer, and ready for use, the obturator should project sufficiently from its lower extremity to make a probe-point. If it does not enter far enough to accomplish this, it will be found either that the thread is too

[1] I have ordered a sixth and larger tube for older children where the largest one as at present made, is not retained.

In making out this table a case seen with Drs. Perry and J. L. Smith, February 3, 1886, was overlooked.

NOTES.

Case 3. Very little relief was afforded, in this case by the introduction of the tube, most of the dyspnœa being probably due to extension of membrane to the bronchi. The respirations were from seventy-five to eighty per minute soon after intubation.

Case 5. Died from uræmic convulsions two days after the removal of the tube and the disappearance of all laryngeal obstruction. The urine upon being boiled became almost solid.

Case 7. Died from exhaustion, due to persistent uræmic vomiting, four days after intubation. Urine scanty and bloody; no dyspnœa.

Case 8. Had a pulse of over two hundred per minute when the tube was inserted, and never rallied.

Case 9. Was septic and had a temperature of 106.4, pulse of 190, when intubated. Died quietly six hours later.

Case 11. Was an imbecile. This attack of diphtheria was preceded by scarlet fever, and at no time could she be induced to take nourishment in any form. Death was due to exhaustion.

Case 12. Was suffering from pneumonia several days before intubation was done. Bronchial breathing still present over greater portion of right lung posteriorly. Death took place from exhaustion. No dyspnœa.

Case 16. The disease in this case began in the larynx, and subsequently spread to the pharynx. Forty-eight hours after intubation the dyspnœa returned, and upon removing the tube its lumen was found almost obliterated by tenacious mucus. While cleaning the tube and preparing it for reinsertion the child became blue and almost asphyxiated. Although such a rapid return of the dyspnœa after removal of the tube is very rare, it is well to be prepared for such an occurrence by having another tube attached to the introducer ready for reinsertion.

Case 17. Was a bad septic case, and hopeless from the beginning. The swelling of the surrounding tissues was so enormous that the cavity of the larynx was obliterated, and could be located with difficulty; and the epiglottis was so distorted that it was by no means easy to insert the tube.

Case 23. Died comatose and without dyspnœa. Persistent uræmic vomiting. The urine gelatinized upon heating, and there was complete suppression for thirty-six hours before death.

Case 26. In this case the dyspnœa returned eleven hours after the insertion of the tube. It was removed, and being found clean was reinserted. Membrane was pushed down before it at each introduction, and it was therefore left out. Death,

thick, or that it is not in the groove corresponding to the hole in the tube.

The child is held upright on the lap with its head on the left shoulder to prevent interference with the gag, the arms are secured by the sides, either by wrapping a towel or a sheet around the body, or by being grasped firmly below the elbows, and held until the tube is inserted and the string removed. Neglect of this precaution will often necessitate a repetition of the operation, as the child invariably seizes the string as soon as it can liberate its hands. The gag is then inserted well back between the teeth, in the left angle of the mouth, and opened as widely as possible without using undue force. An assistant, standing behind the patient, holds the head, with the chin somewhat elevated, by placing one hand on either side, the fingers of the left hand overlapping the gag. If the head is carried too far back, the tube will come in contact with the anterior wall of the larynx or trachea, and some resistance will thereby be offered to its passage.

The operator, holding the introducer in the right hand, inserts the index finger of the left well back towards the œsophagus, and in bringing it forward raises the epiglottis and locates the cavity of the larynx. To the uneducated finger, the cavity of the larynx is a better landmark than the epiglottis, for if the latter is in a comparatively healthy condition, it is not easy to distinguish it, while if the cavity of the former is entered by the tip of the finger, the epiglottis must be in front of it. While fixing the epiglottis the finger is kept as far to the patient's right as possible in order to give room for the tube to enter beside it. In the beginning of the operation the handle of the introducer is held close to the patient's chest, and elevated as the tube approaches the glottis. Very little force is necessary to overcome any form of acute stenosis of the larynx, and if the tube does not enter easily it should be withdrawn and another attempt made. When the tube is supposed to be in the larynx, it is detached from its obturator by pressing forward the button on the upper surface of the handle of the introducer; and in removing it, the movements required for its insertion are reversed. While doing this it is necessary to keep the finger in contact with the head of the tube to prevent its being also withdrawn. Before detaching the tube it should be carried well down in the larynx, otherwise the lower aperture will be left open and liable to strip off membrane, as it is subsequently pushed down with the finger.

As soon as the tube is inserted the gag is removed, but the thread is allowed to remain long enough to be certain that the dyspnœa is relieved. In some cases very little irritation follows the introduction of the tube, and in such it is well to leave the string in position for ten or fifteen minutes in order to excite more cough to get rid of the accumulated secretions, and overcome any collapse of the lungs that may have taken place. In removing the string it is necessary to reinsert the finger to hold the tube down, but it is rarely necessary to use the gag for this purpose as most children will readily open the mouth to get rid of the string.

In removing the tube the child is held in the same position, and the extractor is passed along beside the finger which is brought in contact with the tube, and then pressed towards the patient's right in order to uncover the aperture, and allow the instrument to enter in or near a straight line. Continuous pressure with the thumb is then made on the lever above the handle of the extractor while it is being withdrawn.

The small size of the opening in the tube compared with that of the larynx renders this part of the operation the more difficult. No force whatever is necessary in removing a tube from the larynx, and if any resistance is felt it will be found that the extractor is not in the tube, but is caught in the surrounding tissues.

In cases that progress favorably the tube should be removed on or about the fifth day. In the twelve recoveries reported in this paper the tube was retained, on an average, five days and seven hours. In the youngest of these, aged fifteen months, it was worn nine days, and had to be reinserted on the eleventh day, but was retained then only two hours. The age therefore must be considered in determining the time the tube should be removed. It can, as a rule, be dispensed with earlier in cases of slow, than in those of rapid, development. If loose membrane exist below the tube, which is indicated by a flapping sound with a somewhat croupy character to the cough, it should be left in position until this has had time to dissolve and disappear.

The tube should be removed whenever urgent secondary dyspnœa occurs, as it is often difficult to say whether the obstruction is in the tube, or lower down. A fair respiratory murmur, or numerous râles, over the posterior portion of lungs is the best evidence that there is no serious obstruction in the tube, one-half the calibre of which is sufficient for comfortable breathing.

Not unfrequently a spasmodic dyspnœa occurs soon after the removal of the tube. This is due to contact of the inspired air with the eroded and inflamed mucous membrane which had been so long covered up. It will be more likely to happen where the larynx has been very much irritated by repeated attempts at extraction.

It usually subsides in about an hour, especially if aided by an anodyne. In a recent case of this kind, urgent dyspnœa returned soon after the removal of the tube on the fifth day, and I reinserted a smaller size with the hope that it would not be retained long. It was coughed out

which was certainly hastened by the removal and reinsertion of the tube, took place an hour later.

Case 27. This boy was moribund, with scarcely perceptible pulse. The dyspnæa was relieved, but he never rallied.

Case 30. The development of croup in this was preceded by a severe attack of bronchitis. She died from broncho-pneumonia twenty-five hours after the removal of the tube, and without any return of the obstruction in the larynx.

Case 32. This case is unique as regards my practice, being the only one in which the tube has been swallowed after being expelled from the larynx. It occurred during the night, and probably during sleep, as the cough was noticed to be croupy early the next morning. The tube was passed per rectum on the third day. Although a croupy cough may be caused by loose membrane above or below the tube, it is usually sufficient proof that the tube is not in the larynx. I recall a case where the tube was supposed to have been coughed out and swallowed, but later on was expelled from the larynx; and another case where the tube was believed to have been swallowed, but was found in the pocket of one of the other children.

Case 36. Was moribund when the tube was introduced, and never rallied. The urine was loaded with albumen, and shortly before death the whole surface was covered with a petechial eruption.

Case 39. This was apparently a hopeless case. It was only fifteen months old, and post-nasal, pharyngeal, and laryngeal diphtheria, following measles. Temperature was 105. At the time the tube was inserted it had broncho-pneumonia, from which it recovered. The tube was removed permanently on the eleventh day. The convalescence was slow, but the recovery was complete.

Case 41. This case is of interest from the fact that the dyspnœa was relieved for two days, although the tube was retained only two hours after its first introduction (the operation was performed by Dr. F. Lange). I reinserted the tube on the recurrence of the dyspnœa, and it was retained probably because the patient did not have sufficient strength to cough it out.

Case 42. No membrane appeared in the pharynx at any time, but pieces and shreds were expectorated. The laryngeal symptoms followed immediately on exposure to cold, walking in the snow without covering on the feet. It would be regarded as a typical case of membranous croup by those who believe in such a disease.

Case 45. Coughed out tube on second day, filled with a cast of the trachea. The dyspnœa rapidly returned, and in three hours the tube was reinserted. Death took place from extension to the bronchial tubes.

Males, 27; females, 23. Total 50. Recoveries, 12. Average age, two years and nine months.

It will be observed that 18 cases with 2 recoveries were under three years of age; 12 cases with 2 recoveries, between three and four years; 7 cases with 4 recoveries, between four and five years; 5 cases with 2 recoveries, between five and six years; and 8 cases with 2 recoveries, between six and eleven years.

in twelve hours, and there was no return of the obstruction. I have tried cocaine spray in two such cases without benefit. Giving an antispasmodic about an hour before the intended removal of the tube will tend to lessen this difficulty, and to allay the persistent, irritating cough which sometimes follows the removal of the tube, and which nothing so promptly relieves as its reinsertion. Coating the upper part of the cannlar with gelatine containing a large percentage of cocaine would probably fulfil the indications better than anything else. I tried this plan in two cases of croup on the first introduction of the tube, but found it objectionable from the fact that it diminished the cough, which is so essential to get rid of the secretions. I am now using the gelatine, applied in this manner, medicated with Boric Acid which combines mild astringent with antiseptic properties. It must be remembered that this form of application is a continuous one, extending over not only hours but probably days, and consequently that the drug used should be mild. I was forcibly convinced of this about eighteen months ago when I tried powerful astringents, applied in a similar manner (see article on Intubation of the Larynx in Wood's Reference Handbook of the Medical Sciences vol. IV.)

Gelatine swells considerably as it absorbs moisture, and will produce painful dilatation if the tube is coated too thickly with it. I took advantage of this quality in a recent case of stenosis of the larynx, in an adult, due to syphilitic subglottic swelling of the mucous membrane, with excellent result. It was so applied that the pressure was exerted only on the swollen tissues. This method of making applications to the larynx, not only in croup, but in other forms of stenosis is worthy of an extended trial.

There is no doubt that, after intubation, some of the fluids swallowed enter the tube, while solids do not. The explanation of this is found in the property of fluids to press equally in all directions, and when forced downwards by the muscles of deglutition the epiglottis is lifted, no matter how accurately it covers the aperture of the tube. There is no danger of vomited matters entering the air-passages in this manner, as there is no resistance offered to their escape from the pharynx. There is, consequently, no objection to the use of emetics, if indicated while the tube is in the larynx, except that it is more likely to be expelled by vomiting than by coughing.

One of the greatest objections urged against this operation is the alleged danger of exciting pneumonia from the entrance of food or medicine through the tube. Although pneumonia is not an uncommon sequel of intubation of the larynx, and of tracheotomy, I believe the principal factor in its causation after both operations is the impairment of the expulsive power of the cough from inability to close the glottis, and the consequent retention of the irritating secretions in the bronchi, and not the entrance of extraneous substances through the tube. The first part of the act of coughing is accompanied by complete closure of the glottis which retains the air until it has undergone sufficient compression to give it frictional or expulsive power. With a tube in the larynx or trachea, any considerable degree of compression is impossible, as it is equivalent to coughing with an open glottis. But no one who has seen both operations will deny that there is more power to expel secretions through the laryngeal than through the tracheal canula. This, I believe, is due principally to the smaller calibre of the former, which prevents the air from escaping so rapidly, aided, probably by the epiglottis, pillars of the fauces, etc. Atelectasis and congestion from extreme stenosis of the larynx, or from plugging of some of the bronchial tubes with pseudo-membrane, is another not uncommon exciting cause of pneumonia in croup.

In the great majority of the autopsies that I have witnessed in this disease the cause of death after operation was extension of the croupous inflammation to the bronchi, and pneumonia could not be demonstrated without the aid of the microscope. The lungs, as a rule, presented the gross appearances of simple collapse with an abnormal amount of blood, and responded perfectly to the inflation test. Emphysema of the anterior borders, sometimes interstitial, existed in almost all. Acute general emphysema, due to expiration being more obstructed than inspiration, either in the larynx or by loose membrane lower down, acting as a valve which permitted the air to enter more freely than it could escape, was present in only a few.

It would be useless to enter into any discussion of the question as to whether pneumonia is more or less common after intubation than after tracheotomy, while there exists such a wide difference of opinion as to the frequency of this complication following the latter operation, some authorities claiming that it is rare, others that it is extremely common. Steiner, for example, who writes the article on croup in Ziemssen's Cyclopædia, found pneumonia only fourteen times in seventy-two autopsies. Peter found it in three-fourths, and others in as many as five-sixths of their cases.

A similar difference of opinion also exists in regard to the percentage of recoveries after trachiotomy in croup. Those who have not seen much of the operation themselves, accept the published reports as indicating about the average results obtained. These I know from my own experience with the operation, extending over several years, and from conversations with a large number of physicians on the subject, to be far from the truth.

For several years past there have been, from seven hundred to one thousand deaths in this city annually from croup, and if tracheotomy were resorted to in only one-fourth of this number, which is a very low estimate, it would give an average of about two hundred cases a year, without the recoveries. Every careful reader of the medical literature of this city knows that only a small fraction of this number ever finds its way into print, and I believe there is only one explanation for it, viz., that, with rare exceptions, only the few operators who have good results publish their cases, which is a mere bagatelle compared with the whole number operated on.

With a view to obtaining more reliable statistics on this subject, if all those who practice intnbation of the larynx in the treatment of croup will report their results whether good or bad, and at the same time give the results they have had with tracheotomy, in a few years a sufficient number of cases will have been accumulated to give something like a true estimate of the percentage of recoveries from both operations, and render a fair comparison of their merits possible.

Dangers of the operation.—Some of the following accidents that occur in practicing intubation of the larynx are avoidable, and are due to want of previous practice on the cadaver. These will diminish as the operation grows older, and a greater number acquire proficiency in performing it. Nothing could be more erroneous than the prevalent opinion that it is an easy matter to place a tube in the larynx or remove it, and I am satisfied that a single trial will serve to convince most persons of this fact. Only the few who possess an unusual amount of dexterity, combined with coolness, will succeed on their first attempts without inflicting unnecessary suffering on their patients, and doing much injury to the larynx as well.

The first accident liable to happen is apnœa from prolonged efforts at introduction. There is very litttle danger of this if the time occupied in such attempt be not more than ten to fifteen seconds.

2. The anxiety to succeed quickly will tempt the operator to use force, thereby running the risk of making a false passage. I was present at the autopsies on two cases in which such an accident occurred. In one, the tube was forced through one of the ventricles and down through the cellular tissue on the outside of the trachea. In the other it was passed through the anterior wall of the œsophagus between it and the trachea, compressing the posterior membranous wall of the latter, and giving

rise to asphyxia. The suspension of respiration in these cases was supposed at the time to have been due to pushing down membrane, as the operators were not conscious of having used force. To avoid this accident the introducing instrument should be held lightly between the thumb and fingers, with the thumb resting on the upper surface.

3. Injury to the larynx in removing the tube by passing the extractor down on the outside of the latter, opening it widely and removing it with force. During practice on the cadaver I have thus seen the cricoid cartilage completely cut through, and the glottis so much increased in size as to permit the tube to slip through into the trachea. If the extractor is in the tube, no resistance whatever is felt in removing it. To obviate this danger as much as possible I have added a regulating screw to this instrument, so that the distance the blades will open can be graduated according to the size of the tube.

4. The most serious of the unavoidable accidents liable to occur is pushing down membrane before the tube in sufficient quantity to produce asphyxia. This has happened to me several times on reinserting the tube, on account of secondary dyspnœa. But in the one hundred and thirty-six cases thus far operated upon, this accident has occurred but once, and that quite recently, on the first introduction. The tube was immediately removed when a cast of the trachea was expelled, and the dyspnœa still remaining, it was reinserted with complete relief.[1]

5. Coughing out the tube before the stenosis has been permanently relieved is seldom attended with any danger, as the dyspnœa is usually relieved for several hours afterward.

6. Blocking up of the tube with masses of pseudomembrane too large to pass through has happened in only two of my cases, and in each the tube filled with membrane was expelled. A case has recently been reported where death took place from this accident. Where masses of membrane are suspected to exist low down in the trachea it would be safer to use a smaller tube than the one indicated by the scale of years, as this would be more readily expelled if occluded. I have had short tubes of large calibre constructed for such cases, and also an instrument for removing membrane from the trachea, but have not yet had occasion to try them.

7. The lumen of the tube sometimes becomes slowly but seriously encroached upon by adhesion of the tenacious secretions in those cases of croup that are called dry, particularly if there is very little cough. In such cases the tube must be removed for the purpose of cleaning. I have often given undiluted whiskey or a mixture containing carbonate of ammonia to excite cough in such cases. Those that cough the most, provided they get sufficient sleep, as a rule do the best.

If vomiting occur while attempting to insert or remove the tube, which seldom happens except as the result of recently administered emeties, the operation should be suspended and the gag removed, to avoid the danger of some of the contents of the stomach entering the air-passages.

Treatment of Eye-diseases at Professor Von Hipples' Clinic at Giessen, Germany.—The modified Graefe is the accepted operation for cataract enucleations by the German method, scissors and forceps alone being used to remove the eye-ball. Strabismus operations are done by the Graefe method, dilatation of strictures of the lachrymal canal with Bowman's probes, small size. Tattooing of the cornea is done at one sitting. Ulcers of the cornea are treated with ung. hydrarg. ox. flav., gr. ½ to 3 j. and atropia, and the actual cantery, probably the best and most efficient way of treating this disease.—*Correspondence Medical and Surgical Reporter.*

A New Disinfectant used by Esmarch is creolin. It is said to be much superior to carbolic acid.

PREDISPOSING CAUSES OF DISEASE IN EARLY LIFE.[1]

By HENRY DWIGHT CHAPIN, A.M., M.D.,

PROFESSOR OF DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

It has been my custom for some time past, in examining sick infants and young children, to look carefully for certain underlying conditions, that, if present, will modify both prognosis and treatment. I have been surprised, in so doing, to note how frequently constitutional states may alter the duration and severity of diseases in early life. Young protoplasm is quickly recuperative, and when the source of irritation is removed should speedily return to a healthy condition after inflammatory action. If this do not happen there must be some vice of system to explain a delayed recovery. The very existence of some of the diseased conditions in early life seems to depend largely upon systemic changes. Reference is here made to a perverted or morbidly arrested growth and development. Defective tissue-formation with malnutrition affords a favorable ground for pathological activity. According to my observation, the commonest predisposing factor to disease in infancy and early childhood is a condition of incipient rachitis. This is very different from the severer type of disease, when bony deformity has ensued, and the nature of the disturbance is plainly apparent. I would emphasize the fact, already noted by a number of observers, that a mild form of rachitis is exceedingly common among all classes, and its pernicious effects are especially seen in predisposing to disease and modifying its action. Before dwelling more upon this point, it will be well to glance at the symptoms pointing to a condition of incipient rachitis. A restless, fretful baby, whose sleep is uncertain, but yet who presents no marked evidence of disease, is often alike puzzling to mother and physician. Inquiry will probably reveal the fact that it is almost impossible to keep the suitable coverings on at night. As they are kicked off it will be found that while the body is hot and dry the head and neck are moist with perspiration. A young child should always sleep quietly at night; if it do not, there is some source of irritation. It may be a temporary indigestion, but if such a state continue, there is probably a rachitic condition present. Fretfulness during the day is especially noticeable when the child is moved or handled. If let alone, it is tolerably quiet. This is an evidence of a general tenderness, which is probably located principally in the muscles. If this is very marked, the infant will make no effort to walk at the proper age, and such disinclination may even simulate paralysis. I have in a number of cases known such a condition to be confounded with ordinary infantile paralysis.

Dentition is delayed, perhaps, until nine, twelve, or eighteen months, and the teeth, when they do appear, are apt to be badly developed. Delayed dentition, even with an absence of other symptoms, means almost surely a rachitic condition. I have met with a few instances in which infants, undoubtedly, rachitic, got their teeth quite early. A persistent, subacute indigestion, with loose bowels, is both a cause and effect of this trouble. The earliest bony change, and in incipient cases often the only one noted, is some enlargement at the costochondral articulation. As a result of even slight softening of the ribs, the chest may be somewhat distorted, and any subsequent disease of the lungs be rendered graver and the prognosis more uncertain. It is not necessary to describe the well-known bony changes of more advanced rachitis, as we are now dealing only with an early stage of the trouble. Dr. Gee considers that thirty per cent. of sick children under the age of two years are rickety. In such cases the tissues are in a state of irritability, from the presence of lactic acid or some other

[1]Read before the Clinical Society of the New York Post-Graduate Medical School and Hospital.

noxious agent in excess. Heitzmann, in artificially producing rickets in the lower animals by the administration of lactic acid, noticed catarrhal inflammation of the conjunctiva, of the mucosa, of the bronchi, the stomach, and the intestines, with emaciation and convulsive movements of the extremities.[1] If the irritating agent be not in such excess as to seriously attack the bones, through the epiphysial cartilages and periosteum, it is very apt to produce a disturbance of the mucous membranes. The slightest exposure of a rachitic child usually results in bronchitis. Such an attack is very likely to prove obstinate to treatment. Collapse of air-tubes, with collection of muco-pus, may eventuate in a pneumonia, or, at any rate, render the prognosis grave. If there is deformity of the chest, preventing free expansion of the lungs, a simple pneumonia may become chronic, and death result. Even a slight bronchitis occurring in a rachitic child should receive early and careful treatment. All exposure must be rigorously avoided, and a more guarded prognosis given than would otherwise be thought necessary. Pertussis is an unfortunate accident for a rachitic child, as severe pulmonary trouble is liable to develop. Any intercurrent disease, particularly such a one as measles, will probably be severe. Persistent indigestion with diarrhœa results from the irritable condition of the mucous membrane of the gastro-intestinal tract, and is often difficult to treat. Great care will have to be exercised in withholding food that readily ferments, as an over-acid condition of the intestinal tract is so generally present. While this exists it is almost impossible to give these cases much relief. The nervous system of these children is in a condition of very unstable equilibrium, the worst effect of which is seen in the tendency to convulsions upon the slightest irritation. A cause that in a healthier child would have very little effect may produce a severe or even fatal spasm in a rachitic child. I recently had sent to me from out of town, a boy six years of age who had had four or five convulsions at intervals of several months. It was doubtful whether the case was one of epilepsy or not, but as the child presented evidences of rachitis, with a history of occasional attacks of acute indigestion, I think the convulsions can be thus explained, and the case does not justify heroic and prolonged doses of the bromides, but rather treatment aimed at his general health.

Another common condition of early life that causes great susceptibility to disease is scrofula. The tissues here possess an especial liability to a low grade of inflammatory action characterized by cell-proliferation and a tendency to cheesy degeneration. This state may exist from birth, or apparently be induced by some intercurrent disease. As is well known, cutaneous and mucous surfaces are very often affected by scrofulous inflammations. The neighboring lymphatic glands undergo hyperplasia, which remains after the primary source of irritation has subsided. Tracheo-bronchitis, either primary or secondary to measles and pertussis, often becomes very intractable in scrofulous subjects. Pneumonia will readily ensue, and if so, the chances of caseous degeneration are greater than usual. I have seen such cases neither die nor get well, but drag on for months, perhaps eventually undergoing a partial recovery with a crippled lung, but more probably succumbing finally to exhaustion, induced by the disease. Entero-colitis is readily contracted, and apt to be obstinate to treatment. Vaginitis is likewise rather common. Hypertrophic tonsils usually develop in scrofulous children. I cannot help thinking that some of the symptoms for which they are held responsible are really due to the faulty nutrition of the child coexisting with its scrofulous condition. It is not necessary in this connection to touch upon the affections of the special senses induced by a scrofulous state. Congenital syphilis is a condition that will predispose an infant or young child to disease, especially of the viscera. The manifestations of specific trouble in early life may be exceedingly irregular and puzzling to the physician. In many cases the poison does not appear to be present in sufficient intensity to produce any pathognomonic lesion. Its action is then manifested in the line of certain developmental changes with defective nutrition. I have often suspected syphilis in watching cases of faulty growth, and occasionally an undoubted specific lesion has confirmed the suspicion. Sometimes an infant suffering from this taint may be plump and well-nourished, but any intercurrent disease will quickly reveal a vice of system. I have recently seen a fleshy baby with a large mucous patch in the mouth which developed after some local irritation. Dr. Moncorvo, in a paper read at the recent International Medical Congress, stated that in an extensive practice in Rio de Janeiro and the province of that name he believed hereditary syphilis furnishes sixty per cent. of the cases of infantile disease. He regards it as the most important factor of infantile mortality, either directly or by the severity which it imparts to the diseases of children.

We have, then, in mild cases of rachitis, scrofula, and syphilis, where these affections present no very marked specific lesions, conditions that derive their principal importance from predisposing to disease and enhancing its severity. The importance of clearly appreciating this truth is seen in the fact that appropriate specific treatment must be added to the management of the local disease in order to be successful. If this were done, many diseases of early life would not drag on to such a weary duration. Illness might likewise be prevented by extra care.

There is not a little in common in some of the lesions and the faulty nutrition induced by these conditions. Exact differentiation is sometimes extremely difficult. Scrofula and syphilis often seem very closely allied, and hard to clinically separate. Rachitis and infantile syphilis may coexist; M. Parrot even considers that the former is a manifestation of the latter condition. Dr. Moncorvo states in his paper that more than two-thirds of the rickety children in his practice show signs of syphilis, and it is rare to find an hereditary syphilitic child whose bones are not deformed by rickets. In this country we fail to find such a close connection between the two diseases. While the exact relation of these systemic vices is not certainly known, the common resultant of defective growth and nutrition will be such an important factor in modifying disease that the slightest taint must be carefully sought. Such investigation should form part of the routine in the investigation of children's diseases.

27 West Fifty-first Street.

[1] J. L. Smith: Diseases of Children.

An Old-time Prescription.—In the *Medical and Surgical Reporter* for July 9, 1887, Dr. Harrison Allen calls attention to a number of classical prescriptions which seem to be in danger of being forgotten. The first of these was published in Dr. Chambers' lectures in London, 1865, and is as follows:

℞ Tincturæ ferri sesquichloridi, ʒ ii;
Strychninæ hydrochloratis, gr. ss;
Tincturæ digitalis, ʒ i;
Misturæ camphor., ʒ x.
Fiat mistura.
Sig.—Two tablespoonfuls twice daily.

Dr. Chambers states that he administered an ounce of the mixture twice a day, in a case of anæmia in which the eyeballs were prominent, and he dwells upon the significance of this form of anæmia seen in young women in whom there is excitement of the heart's action, retarded development of the sexual functions, and enlargement of the thyroid gland.

TRAUMATIC HÆMATOMA OF THE LARYNX.

By J. W. GLEITSMANN, M.D.,

PROFESSOR OF LARYNGOLOGY AND RHINOLOGY IN THE NEW YORK POLYCLINIC.

HEMORRHAGES of the larynx are not of rare occurrence, but they are generally either preceded by a catarrhal affection, or brought on by undue exertion of the vocal apparatus. Injuries of the larynx followed by bleeding, are in most cases the result of severe lesions, f. i. incision through the soft parts, fracture of the cartilages, etc. The following case of traumatic injury to the larynx is presented, on account of its unusual ætiology, and on account of some peculiar features concerning the extent of the hemorrhage.

The patient, a short-set, healthy, laboring man, forty-nine years of age, returned home from work in the evening, June 14th. While quietly walking along, he passed a group of negroes who spoke to him. Not noticing them, he was followed by a tall, burly fellow, who sprang upon him and dealt him a violent blow right on the throat with his fist. The patient reeled, fell down on the pavement, and was unconscious for several minutes. Immediately afterwards he began to spit blood, and on arriving home found that he had lost the power of speech, and felt severe pains in the laryngeal region.

He continued to spit blood intermingled with saliva during the following night, after which time an intermission took place till the 16th, when he expectorated a rather firm lump of coagulated blood in the afternoon of that day. Deglutition was extremely painful, and his nourishment during the first three days consisted entirely of liquid food. The patient complained of a sensation of a foreign body in his throat, which interfered with his swallowing. After six days this distressing condition was materially relieved, and at the same time the voice began gradually to come back. On the 23d day of June he still felt a slight impediment in the throat when eating, and his voice was still hoarse and rancous.

The patient presented himself for treatment June 15th, the day after the assault. As a medical friend of mine happened to be present, we began the examination by carefully palpating the larynx from the outside, but were unable to detect any fracture of the cartilage. At the laryngoscopic examination the first object to be seen was a large, dark red tumor of the shape of a tongue, the broad basis of which originated on the outer portion of the posterior laryngeal wall towards the right. Gradually becoming smaller, it covered the right arytenoid cartilage, extended over the inter-arytenoid space into the interior of the larynx, and terminated with a tongue-like point on its posterior wall. The extravasation was beneath the mucous membrane, and no blood could be seen anywhere on its surface.

The interior of the larynx was normal on the left side. The right ventricular band appeared as an indistinct, dark red body, which almost completely covered the vocal cord. The latter was, during phonation, only visible as a small, red line. Morgagni's ventricle could not be distinguished. The movements of the larynx during respiration and phonation were very feeble on the right side; there was no actual paresis, however.

This condition remained almost unchanged during the first three days. After the patient had coughed up a lump of coagulated blood, June 16th, the swelling appeared considerably smaller, and did not encroach upon the interior of the larynx, extending only to the height of the interarytenoid space. The suffusion of blood into the ventricular band was less, and a large part of the vocal cord visible.

The final examination, on June 23rd, showed continuous improvement, the swelling having disappeared, the interarytenoid space being free. The extravasation was confined to a space of the size of a pea on the posterior lateral surface of the right arytenoid cartilage, and extended outwardly towards the pyriform sinus. In this region there seemed to be a fissure in the mucous membrane, and it is to be assumed that the initial lesion occurred in this place.

The interesting feature of the case is the simultaneous extravasation of blood into the external posterior as well as the interior right part of the larynx.

This will admit of the following explanation. The blow directed against the larynx first caused a fissure of the mucous membrane at the posterior exterior surface of the right arytenoid cartilage, producing hemorrhage. At the same time the pressure of the parts against the spinal column produced a contusion of the larynx, from which resulted an extravasation of blood through the whole thickness of the ary-epiglottic fold, making its appearance on the exterior and interior of the larynx.

The treatment was necessarily of an expectant nature, and consisted mainly in the application of resolvent and slightly astringent sprays.

Since the writer's papers on a similar subject,[1] in which he endeavored to give a complete bibliography of laryngeal hemorrhage, only a few publications could be found in the literature. They are by

THE ÆTIOLOGY AND COURSE OF PULMONARY CONSUMPTION, AS INFLUENCED BY THE CLIMATE AND SOIL OF EASTERN NEBRASKA.[2]

By F. W. MILROY, M.D.,

PROFESSOR OF HISTOLOGY AND GENERAL PATHOLOGY, AND LECTURER ON HYGIENE IN THE OMAHA MEDICAL COLLEGE.

PULMONARY consumption is a disease whose fatality is so great that no excuse is necessary for any attempt to cast an additional ray of light upon it. In recent years constantly increasing attention has been given to its climatic treatment, the profession being driven to it perforce by the comparative failure of all other therapeutic measures that have been employed. Extensive and valuable studies have been carried on by the American Climatological Association, which was organized for this express purpose, and by others, and still much remains to be learned upon the subject.

The writer, having been a resident of Omaha for two and one-half years, has been strongly impressed by the apparent immunity from consumption of the residents of this city, and by the favorable course that many cases under his observation have taken upon coming to Omaha from other places.

For my own information I began to look carefully into the matter, and I present to-day the results of my investigation, hoping they may prove to be of interest to others.

In the current periodical literature, one continually sees clinical reports and climatic studies from various parts of the country—east, west, north and south—but I am not informed of any publication, of any extent, concerning the great central territory of the Missouri valley, in its relation to the disease, or group of diseases known as consumption. About a dozen years ago, a report on Climatology and prevailing diseases was submitted to this society by Dr. James H. Peabody, chairman of

[1] Laryngeal Hemorrhage, American Journal of Med. Sciences, April, 1885.

[2] Read before the nineteenth annual meeting of the Nebraska State Medical Society, May, 1887.

the section ; but at that time the data upon which to base a conclusion were very meagre, and generalizations almost impossible. In the present investigation I have taken as a basis the mortality records of Omaha from April, 1879, at which time the ordinance creating these records was first enforced, to January, 1887, a period of a little less than eight years. By a comparison of these records with those of other cities I have endeavored to arrive at some knowledge of the relative healthfulness of Omaha as regards consumption.

It is my intention at a future time to prepare a clinical report which may still further elucidate the subject, but for the present I omit all clinical evidence.

Through the kindness of Drs. Moore and Leisenring, who have held the position of city physicians during the period covered in my work, I have obtained copies of their monthly report, and I present first a summary of the results of my study of these in the form of a table.

TABLE No. I., showing estimated population of Omaha, with death rate from all causes, and also from consumption.

	Estimated Population.	Whole number of Deaths.	Number in 1000 population.	Number Deaths from consumption.	Number in 1000 population.
1879	26215	282	14.34	28	1.06
1880	30518	462	15.4	39	1.27
1881	39500	540	16.61	37	0.93
1882	49710	590	11.87	48	0.97
1883	52470	556	10.59	59	1.12
1884	55230	731	13.23	52	0.94
1885	59616	582	9.74	44	0.73
1886	70410	585	8.30	65	0.92
Average			12.51		0.995

In this table is shown for each year, covered by the mortality record, the estimated population, the number of deaths from all causes, the average number of deaths from all causes in 1000 population, the number of deaths from consumption, and the average number of deaths from consumption in 1000 population. The estimate of the population, which I have used, is that furnished me by Mr. J. M. Wolfe, the editor of the Omaha City Directory.

I have found it difficult to obtain statistics which are at all general, from which I could gain the same information respecting other cities. Some of the records in existence, like those of Omaha, have never been published, and others are to be found only in the reports of Boards of Health of cities, towns and States. The publications of the National Board of Health and the U. S. Census, I have found most complete. Those of which I have availed myself for purposes of comparison, and which are, perhaps, as conclusive as a greater number would be, are two publications only.

In the mortality tables of the U. S. Census of 1880, under the title of "Grand Groups" is to be found a statement of the number of deaths with their causes in fifty of the principal cities of the United States, for the census year ending May 31, 1880. These are arranged in groups without regard to size, but with respect to location. Of these there are fourteen groups containing from one to eight cities each.

Three groups, which include Buffalo, Chicago, Cleveland, Detroit, Milwaukee, Rochester, Toledo, Cincinnati, Dayton, Louisville and Denver, have an average mortality from consumption of 1.74 in 1000 population. This is almost twenty-five per cent. more than the mortality of Omaha for the same period of time ; and reference to the table shows that the mortality in Omaha for 1880 was greater than that of any other of the years recorded. Of the remaining thirty-nine cities the average mortality is 2.45 times as great as that of Omaha. The average of the whole number is more than twice that of Omaha.

In the report of the National Board of Health for 1885 is to be found an appendix presenting a tabulated statement of mortality in cities and towns in the United States in 1884. For the purpose of comparison, I have selected thirty cities, from the list, some of which are larger than Omaha, and some smaller. Of these, six, viz., Boston, Cambridge, Lowell, Providence, New Haven and Fall River, are New England cities ; six viz., New York, Brooklyn, Philadelphia, Baltimore, Newark and Patterson are situated in the Middle Atlantic States ; six, viz., Richmond, Charleston, Atlanta, New Orleans, Galveston and Memphis are in the Southern States ; six, viz., Buffalo, Pittsburgh, Cincinnati, Chicago, Cleveland and St. Louis are in the lake region and upper Mississippi valley ; and six, viz., Minneapolis, St. Paul, Denver, Omaha, Oakland and San Francisco are in the Western and Pacific States. Thus I have covered every portion of our country.

These cities I have arranged in tabular form, showing in each group the average of population, number of deaths from all causes in 1000 population, number of deaths from consumption in 1000 population, the relation of the rate of mortality from Consumption to that of Omaha for the same time, and finally the average of the thirty cities in each of the above points. For convenience, I have subjoined a statement in regard to Omaha.

TABLE No. II.

SIX CITIES OF	Population.	Deaths from all causes in 1000 population.	Deaths from consumption in 1000 population.	Number times mortality from consumption greater than that of Omaha.
New England	130101	22.6	2.89	3.07
The Middle Atlantic States	391914	22.3	3.01	3.2
The Southern States	86103	26.1	3.38	3.59
The Lake Region & Upper Miss. Valley	303041	19.6	2.21	2.35
The Western and Pacific States	104472	15.5	1.85	1.96
Average of 30 cities	243106	21.2	2.67	2.83
Omaha	55230	11.8	0.94	

Now a glance at the table will show that the lowest average mortality, 1.85 in 1000 population, is found in the western and Pacific cities, and that this is almost twice that of Omaha, while Omaha is itself one of the six cities whose average is taken. The difference is slight between the New England and the Middle Atlantic cities, but each of these groups has an average more than three times as great as Omaha.

There is one very important point not shown in the table, viz., that of these thirty cities there was not one that had as low a mortality from consumption as had Omaha for the same year, and that, with six exceptions, the mortality was more than twice as great.

In order to learn whether the lower mortality of Omaha, as compared to the cities above mentioned, depended upon its smaller size, I selected indiscriminately, from the same list, ten cities ranging from the size of Omaha to one-half its size. Of these the average mortality from consumption was 2.57 times that of Omaha.

The statistics which I have cited all point to the same conclusion, and I do not detain you with more.

Now it may be urged that the average age of the inhabitants of Omaha is below that of most of the cities with which comparison has been instituted, and that as this city advances in years the percentage of deaths from this cause will increase But consumption is not a disease of old age, but rather of youth. Cases in which the ages of patients are between twenty and thirty years

greatly preponderate over the number in any other decade of life, and the disease is rare in advanced life.

Whether the disease is inherited or the vice of constitution which leads to it, unquestionably a very large proportion of the cases of consumption possesses the seeds of their malady in their early childhood. So that, even supposing we take the population of Omaha as we now find it, its average youth would tend to increase the ratio of deaths from this cause rather than to diminish it. But it must be borne in mind that only a small portion of the present population of Omaha is native to it, and consequently that a large element in the causation of the disease, hereditary and early surroundings, must have been encountered elsewhere. Look, for example at the deaths from consumption which occurred in 1880.

The whole number was 39. Of these 17 were under 25 years of age, and 22 over 25 years. At the birth of the youngest of the latter number, *i. e.*, in 1855, there were in Omaha but nine buildings of all sorts[1]. In other words, 22 out of the 39 (viz. over 77 per cent.) were born before there was any Omaha, and it is strongly probable that many of the remainder were not native to the place.

So in 1885, there were 44 deaths, of which 22, or 50 per cent. were over 30 years of age, and thus not of the native population.

If this line of reasoning be carried to its legitimate conclusion it becomes evident that, as the ratio of the population native to the place becomes greater, the influences which hold the mortality so low at present will, if continuing to act, by exerting their force upon the individual from and prior to birth, serve to still further reduce the ratio of deaths from this disease.

I am aware that grave danger of falling into error awaits any one pursuing the study of a subject through the aid of statistics. "That figures do not lie" is true in a sense, and yet in such a study as the present so many influences have a bearing, and there are so many sources of misinformation, and so many opportunities for wrongly estimating these are possible, that even figures may be made to grossly misrepresent. With these things in view, I will not attempt a definite statement by way of conclusion at this point. But, when every allowance is made it seems evident that Omaha is exempt from the ravages of consumption to a very remarkable degree.

Now, granting that this conclusion is true it becomes a matter of great interest to discover to what this immunity is due.

In reviewing the commonly accepted causes of consumption as applied to the inhabitants of this city, there appears no adequate cause for it save the nature of the climate and soil.

Climate has long been regarded as one of the most powerful influences in the production of pulmonary consumption. While all acknowledge the potency of climate a diversity of opinion exists respecting the influence of the various elements that go to make up a "Climate," and as is true in the study of most diseases the weight of opinion has experienced numerous fluctuations with respect to it.

Dr. Jaccound, in his "Lectures on the Curability of Phthisis," states that information derived from writings upon this subject cannot take the place of knowledge derived from direct observation. He states further that the impressions made upon the organisms by different climates, are, to some extent, inependent of the certain and described phenomena which constitute the climatology of a region. It is vain to seek in the table of atmospheric changes for the explanation of that special impression which the climate of a region makes upon the affected organism—an impression, which in fact is indefinable, and of which the cause cannot be ascertained: it must be felt to be understood. This fact constitutes one of the fundamental difficulties of the climate problem."

As a consequence of this, one class of observers maintains that high altitude acts favorably upon diseased lung by relieving it from undue pressure, while another holds that the benefit, if any, comes from the rarity of the air inducing more rapid respiration.

Others contend that solar radiation is the great curative agent, while purity of air and consequent freedom from disease germs is that to which still others pin their faith. Heat, cold, absence of humidity, porosity and soil, have each their advocates.

In order to present at a glance the nature of the climate of Omaha, and to enable one to compare it with the climate of other places favorable and otherwise to consumptives, I have tabulated certain deductions that I have made from the observations of the U. S. Signal Service, at this point. Since the interest in this study centres for the most part in but a portion of the year, I have restricted the statement to the months of November, December, January, February and March, with a summary of the year.

TABLE No. III., compiled from the observations of the U. S. Signal Service at Omaha, Neb.

	Nov.	Dec.	Jan.	Feb.	March.	Year.	
Mean temperature.....	35.2	24.9	20.4	26.5	35.6	49.32	Deduced from 15 yrs. observation, viz. Jan. 1, 1871, to Dec. 31, 1885.....
Normal monthly Precipitation, (inch).....	1.32	1.023	0.589	0.504	1.488	35.454	Deduced from 16 yrs. observation, viz Nov. 1872, to Dec. 1887.....
Average Humidity in percentage of Saturation.....	68.38	72.67	74.37	71.99	67.11	68.24	Deduced from 10 yrs. observation, viz. Jan. 1, 1873, to Dec. 31, 1882....
Mean maximum temperature...	69.	50.6	52.	56	71.8	77.6	do.
Absolute maximum temperature.....	74	74	62	66	80	85.9	do.
Mean minimum temperature...	6.5	—5.5	—10.	—3.9	3	22.3	do.
Absolute minimum temp.....	—6.	—17.	—22.	—16	—7	13.	do.
Average of the sum of clear and fair days.....	21.4	20.5	19.8	19.5	21.4	21.15	do.

In an examination of this table one is not impressed by any one feature of the climate as being extraordinary, or as probably sufficient to account for the immunity from consumption which we have found.

The mean temperature is low though not excessively low. The range between the maximum and the minimum temperature is a wide one, and the mean minimum temperature indicates a severe degree of cold.

One point, however, which is well worthy of notice, does not appear in the tables, *i. e.*, the comparative infrequency of extreme changes during the winter months, for all admit that evenness of temperature is of the greatest importance, whether it be high or low. One of the most striking constituents of climate indicated in the chart is the small aqueous precipitation. For January and February combined, it is only a little over one inch, and for the five months under consideration it is less than five inches, while for the year it is almost thirty-five and one-half inches. This feature of the climate is a strong one, and doubtless has a decided influence in determining its effects.

A comparison of the humidity as indicated in the table in percentage of saturation, with the temperature and precipitation, is very puzzling and requires an explanation.

The percentage of saturation as given for March and November is 67.11 and 68.38 respectively, while for the remaining three months it is from four to seven per cent. greater.

For the other seven months of the year during the same period of observation the percentage of saturation

[1] Johnson's History of Nebraska.

ranges from 60.74 in April to 69.91 in July. In other words during the three winter months, when the temperature is lowest, the percentage of atmospheric humidity is said to be greater than during the seven months when the precipitation is more than fifteen times as great. As the existence of such a state of affairs as this would be a direct violation of the physical laws which govern atmospheric humidity, an error is at once apparent. A suggestion of Mr. George Hass-Hagen, the efficient U. S. Signal officer now stationed at Omaha, will serve to locate the mistake. In order to determine the dew point, two thermometers are placed upon a revolving aparatus, the bulb of one of these having been wetted with water. By the difference in temperature indicated by these the rapidity of evaporation is measured, and from this deduction is made. During any period when the temperature is not below the freezing point this method is reasonably correct, but when the temperature is low, it is found that the moisture becomes ice almost the instant it is exposed, and in such a case the variation between the two thermometers is hardly perceptible. This would indicate almost complete saturation, which is wide of the truth. Could the government afford the use of æther during low temperatures, this difficulty would be overcome.

I have inserted in the chart the results of these observations because no climatic statement is considered complete unless the percentage of saturation is indicated. As a matter of fact they are wholly unreliable, and the same may be said of this portion of the Signal Service record at all stations when the temperature is low.

Of nearly equal importance with the slight humidity in Omaha is the number of fair and clear days. This ranks unusually high, and is of great utility by making out-of-door life more pleasant and safe. The month of March, in particular, which, with its cutting damp winds and rain and sleet and constant change of temperature, in a large part of the United States, is the month most to be dreaded by consumptives, in Omaha is one of the most salubrious months of the year.

For the same period of observation, the sum of the clear and fair days was greatest in July (24.2) and August (24.7), and least in May (17.3). Thus it is seen that the average in March (21.4) is only a little below that of midsummer, while the precipitation for this month is less than one and one-half inches. In a general way I would state that the autumn is clear, free from storms of all kinds, and warm until about the end of December. At this time cold weather sets in and continues steadily, with very few thaws, through January and February, followed by March as already described, which description will apply to the first half of April. It is worthy of remark that more than two-thirds of the annual rain fall occurs in the night, *i. e.*, between six P. M. and six A. M.

The altitude of Omaha is about 1,100 feet above sea-level. The prevailing winds, for the months under discussion are from the north and north-west. The best that can be said of these is that while they are often strong, the great extent of sparsely settled prairie over which they blow must insure a high degree of purity.

Dr. Henry I. Bowditch, in his address on consumption, before the Massachusetts Medical Society, in 1862, stated that soil moisture is one of the chief causes of Phthisis, and that localities where there is a dry soil are comparatively free from the disease.

Dr. Buchanan, in his "Report to the Privy Council," states that dampness of soil is one of the most prolific causes of Phthisis to the inhabitants living upon it.

Laennec, in his work on "Diseases of the Chest," relates an instance in his experience of a nunnery, of which he had the medical charge for a period of ten years. During that time he witnessed the death of the entire membership three times, from Consumption. It was afterward discovered that this nunnery was built in a clay cup, which caused such constant dampness in the buildings that they were abandoned..

From these observations and many others, it appears certain that one of the most fatal conditions is that in which the air is laden with moisture due to an impervious subsoil. This ground-air seems to be filled with germs of special vitality. Hence the nature of the soil is of fundamental importance.

The soil of Omaha and its vicinity is called "Loess," and for a description of this rare geological formation I quote from the work of Prof. Samuel Aughey.[1]

"This deposit is, in some respects, one of the most remarkable in the world. It prevails over at least three-fourths of the surface of Nebraska. It ranges in thickness from five to one hundred and fifty feet. I have compared many specimens taken three hundred miles apart, and from the top and bottom of the deposits, and no difference could be detected by the eye or chemical analysis." "Over eighty per cent. of this deposit is very finely comminuted silica—and about ten per cent. is composed of the carbonates and phosphates of lime." Its drainage, which is the very best possible, is owing to the remarkably finely comminuted silica of which the bulk of the deposit consists. Where the ground is cultivated the most copious rains percolate through the soil, which, in its lowest depths, retains it like a huge sponge. Even the unbroken prairie absorbs much of the heavy rains that fall.

"On the other hand the extremely wet seasons only damage the crops over the low bottoms, subject to overflow. From twelve to twenty-four hours after the heaviest rains the roads are perfectly dry. The soil is easily worked, yielding readily to the shovel or plough. Excavation is remarkably easy, and no pick or mattock is thought of for such purposes."

The physical characteristics and the geological history of this deposit are an interesting study, but enough has been said to indicate the remarkable surface drainage which prevails wherever this deposit is found. In a word, there are no swamps or marshes. No collection of water remains nearer the surface than the bottom of the Loess deposit, and to that depth (40 to 150 feet) wells must be sunk in order to obtain it.

In closing I would offer the following conclusions:

1. The inhabitants of Omaha enjoy immunity from consumption to a remarkable degree.

2. This is in part accounted for by the great degree of solar radiation, and the small humidity of the climate.

3. The Loess formation which covers a large portion of Nebraska, and to some extent adjoining territory furnishes the ideal of perfect drainage, and thereby contributes more than all else to the above immunity.

4. If the meteorological phenomena of this climate necessitate conclusion 3rd, there is thereby furnished additional evidence of the malign effect of surface ground-water in the production of consumption.

SOME SUGGESTIONS IN REGARD TO PERINEAL SECTION OR EXTERNAL URETHROTOMY.

BY SAMUEL ALEXANDER A.M., M.D.,

VISITING SURGEON TO BELLEVUE HOSPITAL.

After external urethrotomy the perineal wound is left to heal by granulation. The length of time which this requires is a great objection to the operation. To shorten this time by obtaining primary union throughout the greater part of the wound, the following mode of treatment may be employed. Antiseptic precautions should as far as possible be observed.

Method of Performing the Operation.—The urethra having been opened in the usual way, and all strictures and bands, especially those on the roof of the urethra, having been divided, the operator proceeds as follows:—The bladder is first emptied and thoroughly washed out with a suitable disinfecting fluid. For this

[1] Sketches of the Physical Geography and Geology of Nebraska, 1880.

purpose I use a strong solution of borax, or, still better, Tiersch's Solution. The urethra, perineal wound, and the surrounding parts are also to be disinfected. A sound is then introduced through the urethra and intrusted to an assistant who holds it in the same position as a lithotomy staff, and at the same time draws up the scrotum out of the way. This sound should be large enough to distend the urethra, so that the cut edges may be seen at the bottom of the wound. The sutures are now to be put in position. For this a strong, well-curved needle, threaded with a double ligature of heavy catgut should be employed. I have used both silver wire and silk, but find it an advantage to have a ligature that does not have to be removed. The point of the needle is entered at about half an inch from the margin of the wound, the tissues should be deeply penetrated, and the point of the needle brought out in the wound as near as possible to the edge of the divided urethra; it is then reintroduced at a corresponding point on the opposite side. The urethra is NOT to be included in the sutures. Three or four sutures are usually sufficient. Before bringing the surfaces of the wound into apposition, the sound is withdrawn. A large, soft rubber catheter (No. 18 A. scale) is then passed through the wound into the bladder. These catheters are called Thompson's perineal tubes, being the same tube as recommended by Sir Henry Thompson for vesical drainage. Care should be taken when selecting a tube to see that the lumen is large. The eye should be as near to the extremity as possible. The tube should comfortably fill the prostatic urethra, and when in position it should occupy the lower angle of the wound, the eye being just within the bladder. The sides of the wound are now brought together, and the sutures may be quilled if necessary. Superficial stitches may be put in if required. To ascertain that the tube is in proper position, a few ounces of fluid should be injected into the bladder, and as this flows out withdraw the tube until the flow is arrested, then re-introduce it until the fluid again begins to flow. In this way the eye of the tube is left just within the bladder. The tube is then secured by four tapes, which are tied about it just at the edge of the wound: two of these are brought forward on either side of the scrotum and two behind which lie in the glenteal folds, and are secured to a waistband.

The wound is now powdered over with bismuth or iodiform and a light dressing applied, which surrounds the tube, the end of which is received into a suitable urinal placed between the thighs.

SUBSEQUENT TREATMENT.—A successful result after this operation depends largely upon careful attention to the details of the subsequent treatment.

MANAGEMENT OF THE TUBE.—It is essential that the perineal tube should not become displaced, and that its calibre should not become obstructed, and thus permit the urine to come in contact with the wound.

The tube at first causes some discomfort, producing a desire to urinate, accompanied with pain in the head of penis. Sufficient morphia should be given to relieve this. In cases complicated by severe cystitis, the perfect rest afforded by the tube to the inflamed bladder is a great relief. The bladder should be washed out with Tiersch's Solution once or twice a day. On the third day after the operation, the tube may be removed. The sinus which remains should be stimulated if necessary, and allowed to heal from the bottom. It should be carefully disinfected after each act of urination, until all urine passes per urethram, and, until this occurs, it is advisable for the patient to lie upon his side while urinating. All of the urine usually passes per viam naturism at or before the end of the second week.

PASSAGE OF SOUNDS.—It is, of course, necessary to maintain the calibre of the urethra by the passage of sounds. The intervals between each dilation depend upon the necessities of the case. The first instrument should be introduced 24 hours after the operation. This must be done with great gentleness, as any violence is liable to re-open the wound. It should be done as follows: Wash out the bladder and then withdraw the perineal tube. If the urethra is very sensitive, cocaine may be used with advantage. Inject the urethra with carbolized oil, or cosmoline, then slowly introduce the largest conical steel instrument that the urethra will admit. This should be previously disinfected, warmed and plentifully lubricated. The roof of the urethra should be followed as a guide to the bladder, and it is not necessary to depress the handle of the instrument completely. The sound being withdrawn, the perineal tube is re-introduced.

GENERAL DIRECTIONS.—The dressing should be changed as often as necessary. The patient must be kept on his back during the first twenty-four hours. The urine is to be kept bland by the use of diluents, such as Poland or Bethesda water. It is better to confine the bowels during the first three days and then to give a laxative, and aid their passage by enemata. The wound is practically healed at the end of two weeks, but the patient may sit up at the end of the first week.

The above suggestions are made as the result of my observation of this method in four cases of simple perineal section. In order to confirm the opinion which I have formed, further trial of this method is necessary. In addition to the four cases mentioned above, I have also, with certain modifications, used this method in two cases of severe perineal fistula. In one of these, it was necessary to restore the floor of the urethra for three inches. Both of these cases did well. On account of the lack of vitality of the tissues, it was necessary to keep the perineal tube in place for one week before the wound united. On this account, recovery was not as rapid as in the cases mentioned above, but the ultimate result was perfectly satisfactory. My house surgeon, Dr. McCann, informs me of two successful results in cases operated upon by him.

The advantage offered by this method seem to afford a wider applicability for external urethrotomy than at present. This question, I propose, in a subsequent article, to discuss.

95 PARK AVENUE.

COLORADO SPRINGS AND DAVOS-PLATZ, AS WINTER HEALTH RESORTS, COMPARED.

BY CLINTON WAGNER, M.D.,

SENIOR SURGEON TO THE METROPOLITAN THROAT HOSPITAL, NEW YORK.

UNTIL within a comparatively brief period, a little over twenty years, it was the universal custom of the medical profession to send cases of phthisis pulmonalis to warm and equable climates, such as Madeira, the Riviera, Italy, Egypt or Algiers; and, on this side of the Atlantic, the favorite resorts were certain of the West India Islands, or our Southern States, and, of late years, Southern California.

A quarter of a century ago, had it been suggested, to send such cases to spend the fall and winter months in a place like Davos-Platz, where the ground for at least six months in the year is hidden by snow, or to Colorado Springs, where the difference between the temperature in the sun, and that of the night is sometimes as great as 130°, the proposition would have been regarded as utterly unscientific, and would not have been seriously entertained for a moment, at least, by the conservatives in medicine.

The Swiss, it is said, suffer more from nostalgia than any other people; it is probably owing to this that, when in foreign lands, they become stricken with phthisis, they return home to die; to the surprise of themselves and friends many recover.

This fact, and the absence of phthisis as a cause of

[1] Read before the New York Academy of Medicine, October 20, 1887.

death, in the statistical reports of certain localities in Switzerland, induced Dr. Unger and one other, both Germans, and both suffering from phthisis, to visit Davos-Platz. This was in 1865; both recovered, and one is still living in the village.

Dr. Hermann Weber, I believe, was the first to advocate the treatment of phthisis, by residence in the cold, dry, rarefied atmosphere of high altitudes; he was followed by C. T. Williams, Barney George Albutt, Wise, Dennison and many others who sustained the practice.

Experience was not long wanting, to establish the truth of the theories, in regard to what was, at that time, novel climatic treatment.

The treatment is no longer experimental; the thousands who have sought Colorado Springs and Davos-Platz, and who have been restored to perfect health, attest the curative virtues of the climates, but there is still, notwithstanding the many excellent books and papers that have appeared from time to time, describing these resorts, great ignorance concerning them, among members of the profession, who still cling to the practice as taught from the earliest periods, of seeking equability and warmth, as the chief desiderata in selecting residences for their cases of phthisis.

In the following paper I shall give only the result of my *personal observations* from residence in both places, and which, I trust, will aid in removing the erroneous impressions that have formed in the minds of many, especially in regard to the fitness of Colorado Springs, as a Winter Resort for cases of phthisis. As I have already stated, the aim of the majority of the profession, until quite recently, has been to find equability, warmth and dryness, in selecting places of resort for phthisical cases.

There is no section that can claim all three of these qualities—you can find dryness and warmth, or equability and warmth, but you cannot find equability and dryness. The subject of atmospheric moisture and dryness has been most exhaustively investigated by Dr. Davison of Denver, in several able monographs, to which I must refer you for further information; especially that of a statistical nature. In one of his papers, he states that "statistics prove beyond the possibility of successful contradiction, that variability is a distinguishing attribute of really dry places—whether elevated above sea-level or not, and that equability is, as a rule, characteristic of a uniformly damp atmosphere."[1] It only remains then, to be shown that dryness and variability, with abundance of sunshine, the characteristics of the two resorts under consideration, are more curative of phthisis than resorts on the Riviera, or in Florida, or other semi-tropical places, where the opposite conditions obtain.

The town of Colorado Springs is seventy-five miles south of Denver, and is situated upon a broad stretch of table land, near the foot-hills, which lie at the base of the most eastern spurs of the Rocky Mountain range. It is in latitude 39° and longitude 105. It has an elevation of more than 6,000 feet above the level of the sea, and five miles to the west is Pike's Peak, the summit of which is 14,200 feet feet above the sea. On the north and west it is sheltered by the mountain range, but is quite open to the east and south. The town was laid out in 1871, by parties from Philadelphia, and its broad avenues and streets running at right angles to each other, and planted with rows of beautiful shade trees, are suggestive of that city.

In describing a climate, which presents so many anomalies as that of Colorado Springs, for instance, the dryness of an inland desert, the cold, bracing air of the far north, an atmosphere so clear that mountains one hundred and thirty miles distant can be seen distinctly, without the aid of a glass, the sun of the tropics, a sky that surpasses that of Italy in loveliness, and scenery which compares with that of Switzerland, one may justly stand in dread of being charged with indulging in the language of the imagination. However, I shall attempt it, and give a plain statement of my personal impressions. From September, till the latter part of April or May, no rain falls; there are no fogs, no mists, and rarely frost; snow occasionally falls, but does not remain longer than a day or two. It disappears by evaporation, or like chaff before the west wind, which in winter is warm and highly electrical, or it is absorbed by the sandy, porous soil.

The sun shines three hundred and thirty days of the year, or, if we take the six winter months, from October 1st to April 1st, usually the worst months in regard to weather for invalids, in other sections, one hundred and sixty-five days out of the one hundred and eighty-two, will be days of sunshine—or an average of less than one-half day in each week, that the invalid will be deprived of sunshine.

In the sun the temperature is warm and equable, it is never cold, and during midwinter, and in fact during the entire winter, invalids sit on the piazzas of their houses in the open air, without the necessity of providing extra wraps. The thermometer when exposed to the sun's rays indicates from 90° to 130° of heat, and there is always a difference of at least 50° between the sun and shade.

This extrordinary intensity of the sun's heat is due to the fact that the air is so clear, rarefied, and free from moisture, that but little resistance is offered to the transmission of its rays. The surrounding atmosphere remains cold, at times very cold, the mercury falling to zero and even below. If the atmosphere were not cold and dry, the heat of the sun would be almost intolerable. During the night, the mercury not unfrequently falls to 4° or 5° below zero. I have known it to reach 25° below zero. But notwithstanding this extraordinary difference between the day and night temperature, during the hours of sunshine, from 8 a. m. to 4 p. m. for the shortest days, the invalid may venture out of doors, and remain for hours without risk. The most disagreeable feature of this remarkable climate is the wind—November and March are the most windy months. During November, every fifth or sixth day, a violent wind storm prevails for a few hours; but there are days, and I may say weeks, in which there will be but little if any wind, certainly not sufficient to compel the invalid to remain in-doors. Upon the whole, there is less wind at Colorado Springs than I experienced at the famous resorts on the Riviera, where the irritating and disagreeable mistral blows for days at a time.

In diseases of the respiratory organs, residence at Colorado Springs is especially beneficial. In cases of phthisis pulmonalis, whether catarrhal or tubercular, stationary or progressive—chronic or bronchial catarrh, the results of pleurisy and pneumonia, improvement or recovery may be looked for. Dr. Anderson, who has been engaged in active practice in the town for fifteen years, informed me that he has known several cases of well defined pulmonary cavities *recover*.

The effect of the dry rarefied air is to increase the appetite; assimilation is improved, the number and depth of respirations are increased, the chest gains an expansive power, more moisture is exhaled than in humid atmosphere, the effect of which is, in time, to check secretion from the diseased tissues. The cheeks fill out, the complexion becomes of a ruddy brown, the strength rapidly increases, the spirits revive, and the invalid becomes impressed with the idea that he will recover.

There is a class of invalids who should never be sent to high altitudes; I refer to those of an irritable, nervous or hysterical temperament, in whom there is a tendency to vascular excitement from slight causes. The air is too exciting, too stimulating, and, for such cases, resorts should be found at a lower level.

It is generally taught by writers, and accepted by the resident physicians at high altitude resorts, that laryngeal phthisis will be aggravated by the stimulating character of the atmosphere, and the variability of the climate, and

[1] Moisture and Dryness, or the Analysis of Atmospheric Humidities in the United States.

consequently such cases are advised to seek a warm and equable climate. If it could be satisfactorily shown that this most fatal form of tuberculosis recovered under influence of an equable climate, then this procedure would be eminently proper, but under the circumstances, I think further experience is wanting, before condemning high altitudes, for the relief or cure of these cases.

While at Colorado Springs I saw many cases of phthisis pulmonalis that had recovered, and others that were advancing towards recovery—accordingly, when I was called in, in consultation, to advise concerning several cases of laryngeal phthisis occurring in connection with pulmonary trouble, and in which marked amelioration of the physical signs had already taken place, together with improvement in the general health, I advised that the cases remain at Colorado Springs. I had the satisfaction of seeing one case, a well marked, typical case, recover, and one other greatly improved, and apparently in a fair way to recover. My friend, Dr. Anderson, has informed me that he has had one case recover.

Although my experience is limited to the above cases, I think that cases of laryngeal phthisis may safely be permitted to remain at high altitude resorts, *provided*, improvement in the pulmonary trouble and general condition has already taken place.

In certain other affections of the upper air passages, for instance, nasal and naso-pharyngeal catarrh, I do not regard residence at high altitudes of especial benefit. At Colorado Springs, where the atmosphere is cool, dry and rarefied, and where, at times, there is much wind and dust, I found these affections very numerous.

At Davos-Platz, where the same atmospheric conditions obtain, without the wind and dust, these diseases were quite as prevalent, and at resorts on the Riviera, which I visited, where I found a warm, equable, and moist atmosphere, I encountered many cases. Like other acquired diseases which afflict the human family, I think these are ubiquitous, and, for relief, the patient must rely upon the remedies of the physician rather than climatic influences.

At Colorado Springs the invalid will not be deprived of the luxuries, comforts and conveniences of his eastern home. He can have his choice of living in a hotel thoroughly good in all its appointments, or in an excellent boarding house; or, still better, furnished houses may be rented at reasonable rates, having hot and cold water, gas, etc.

The markets are well supplied with game, fresh meats, fruits and vegetables. There are excellent schools, and also churches of every denomination: there is a theatre, in which many of the troops *en route* to San Francisco, give one or more performances; there are several circulating libraries and a club. The society of the place, composed chiefly of former residents of large cities, is all that could be desired. Horses are very cheap, either for hire or purchase; riding, especially, is recommended by the local physicians. Davos is an alpine valley in south-eastern Switzerland, about 5,300 feet above the level of the sea, and running N. N. E. to S.S. W., averaging about one half a mile in width, and protected by mountain ranges from 2,000 to 5,000 feet above its floor. The village proper is built upon the sides of the mountain above the valley, in order to obtain the greatest amount of shelter from the North wind.

The climate, in many respects, resembles that of Colorado Springs; the intensity of the sun's rays at times is quite as great; the temperature in the shade averages lower, ranging from zero to about 25° above.

The North wind, although the current is scarcely, if at all, felt in the village, brings clear skies, warm sunshine and an intensely cold, bracing atmosphere. The South wind, or föhn, as it is called, is warm, irritating, enervating, and disagreeable alike to the invalid and the strong. During its prevalence, the sky becomes cloudy, and in the early morning a fog or cold, gray mist hangs over the valley, until moved by the wind, or dissipated by the sun; the snow melts rapidly, and the atmosphere becomes very humid; the valley being more open to the south, the full force of this unpleasant wind is felt; it is usually the precursor of a fall of snow. Snow begins to fall in the latter part of October, varying, for each fall, from a few inches to one or two feet. The ground remains covered until the early part of April.

The days are very short. I mean the invalid's day. The sun does not rise until 10 o'clock, and sets at 3 P.M. An hour is devoted to the mid-day meal, thus reducing the invalid's outing to about four and a-half hours.

Cases of the same character are sent by the physicians in Europe to Davos, as those who derive so much benefit from residence at Colorado Springs. So far as I could judge as a mere observer, without the opportunity of making personal examinations of patients (not being engaged in practice), those who were very ill, or rather the cases that appeared to be of a very serious nature, did not improve; some died, and others were in a worse condition in the spring than at the beginning of the season.

Dr. W. R. Huggard, an intelligent physician and careful observer, who is actively engaged in practice at Davos, in an interesting paper[1] says, "The high-altitude treatment offers little prospect of improvement, when a large portion of lung-tissue is involved. The length of time the mischief has been going on is of comparatively little moment, provided always the disease is limited in extent."

On the other hand, cases of most extensive infiltration of lung-tissue, and even of cavities, have been known to recover after a prolonged residence at Colorado Springs.

I think Davos is better suited to cases of incipient phthisis, and to those who retain a certain degree of robustness; who are able to indulge in the active out-door sports of skating, and tobogganing. Walking, for those enfeebled by long illness, is difficult on account of the snow, and tiresome through want of variety; the air is too cold for them to sit out-doors, or to drive when there is no sunshine. To this class the mere presence of snow is apt to convey a feeling of chilliness or cold.

By enumerating a few of the points of difference between Davos and Colorado Springs, the advantages of the latter will become apparent.

At Colorado Springs, in a given period, one month, for instance; there will be twenty-eight good days; at Davos only twenty. At Colorado Springs, during the shortest days of winter, the invalid may enjoy eight hours of sunshine; at Davos only four and one-half hours.

At Davos, out-door amusements are restricted to [illegible] it a valvulitis, and obviate, possibly, the liability to se chronic nutritional changes in the valves wherein after all, the main danger.

HEREDITARY TREMORS.—Dr. C. L. Dana, of New k, calls attention to a peculiar hereditary motor dis- r which has not heretofore been systematically de- hed, but which he has seen, and studied in three ies. The affection consists of a fine tremor, con- ind for a brief time, affecting nearly all the voluntary Spes, chronic, beginning in very early life, not pro- erve, not shortening life, not accompanied with pa- s or any other disturbances of nervous function. It tibles to some extent the tremor of paralysis agitans, Anore a simple neurasthenic tremor. A most striking wal feature is its marked hereditary or family type, and ansmission along with other nervous diseases. It be- din infancy or childhood, sometimes being brought oy an infectious fever. It continues without pro- ing in severity during a lifetime, which it does not oen. The family history will reveal neuroses or psy- a·s. The upper extremities are most noticeably af- od, but it may involve the head, neck, eye, laryngeal, – fine, any of the voluntary muscles. It ceases dur- eep, and can be inhibited temporarily by the will.

and guide books, until at last a most effective system of drainage was constructed, regardless of cost. It is now claimed that it is the best drained health resort in Europe.

I regret that I cannot say as much for Colorado Springs. In this most important matter, Davos has certainly a very great advantage. Colorado Springs has practically *no system of sewerage*; as a receptacle for waste water and slops, the cesspool is still used, and sometimes it is in dangerous proximity to the dwelling houses. It is time the cesspool has ventilating pipes, but I do not regard them as at all effective. In lieu of water closets, the old fashioned privy—a mere hole in the ground—is used for the majority of the houses. The question of building a system of sewerage has been under consideration for some time past. The town, being built upon a plateau, which slopes to the west, east and south, it could be done to perfection, and I believe will be done at an early day. The leading hotel, The Antlers, I am glad to say, is drained in the Monument Creek, which runs north and south about 300 yards west of the hotel.

Davos, with all its drawbacks, is unquestionably the most desirable of the high-altitude resorts in Europe, but it is with the object of impressing upon you the superior advantages of Colorado Springs that I have given the result of my observations.

Much stress is laid, by the admirers of Davos, upon the purity of the air, and the absence of wind and dust.

The village is overcrowded, and the number of hours out of the twenty-four that the invalid is compelled to remain in-doors, counteract in a great measure the beneficial effects of the out-door life.

But, for those who prefer the peculiar features of Davos, we have Mariton, which has an elevation of 1,000 feet greater than Davos; it is five miles west of Colorado Springs, and fifteen minutes by rail. It is perfectly sheltered from the wind, quite as much so as Davos; there is no dust, and the ground is covered the greater portion of the winter with snow; the shortest days have six hours of sunshine. There are also excellent iron and soda springs, with baths of the latter, either hot or cold.

I must mention also that Mariton was a winter resort, before the city of Colorado Springs was built; but the invalids, wiser than the physicians who sent them thither, learned that days with abundance of warm sunshine, with occasional wind, were more beneficial than being shut in by high mountain ranges.

During the winter Mariton is now practically deserted, but, during the later spring and summer months, it is the resort of thousands, seekers after health and pleasure.

---

where the opposite conditions obtain.

The town of Colorado Springs is seventy-five miles south of Denver, and is situated upon a broad stretch of table land, near the foot-hills, which lie at the base of the most eastern spurs of the Rocky Mountain range. It is in latitude 39° and longitude 105. It has an elevation of more than 6,000 feet above the level of the sea, and five miles to the west is Pike's Peak, the summit of which is 14,200 feet feet above the sea. Clinical Department.

HERNIOTOMY UNDER COCAINE ANAESTHESIA.

Dr. Charles S. Godfrey, of Bridgeport, Ct., writes: "Having read an article in The Medical Record of September 24th, on Herniotomy under Cocaine Anaesthesia, I would say that I so operated on a patient in July 7, 1886.

"Mrs. S., of Bridgeport, Ct., age about 60, had had right femoral hernia of several years' standing, which was kept in place by an ill-fitting truss. On July 6th I was called to see her on account of pain in the abdomen. I found the heruia down, in which condition, the patient informed me, it had been for four days, she being unable to reduce it. I employed taxis without effect, and ordered applications of ice, to be continued at intervals through the night. On the following morning, still being unable to return the gut into the abdominal cavity, I operated with the assistance of my partner, Dr. S. M. Garlich. As the patient had a bad mitral regurgitant and aortic obstructive murmur, with considerable difficulty of breathing at times, we advised the use of cocaine. The first incision through the skin was made quickly with a sharp scalpel, and the raw surface was painted with cocaine (4 per cent.) solution by means of a camel's hair brush; the dissection was then continued, more cocaine being applied from time to time. The constriction was found at the inner ring, which was cut, and the intestines were returned to the abdomen. A silver wire was carried through the pillars, and the external wound was closed by catgut sutures. The operation required about twenty minims of cocaine, and was conducted with strictly antiseptic precautions. In one week, the dressings having become loosened, I examined the parts and found complete union. The silver wire I removed in fourteen days.

The only pain felt by the patient was at the time of the first incision, and upon the introduction of the silver wire, but it was not sufficient to cause distress. The patient has had no return of the hernia since the operation."

COCAINE HALLUCINATION.

Dr. Amory Chapin, of this city, writes, that he read the article in The Medical Record on cocaine by Dr. Ring, with special interest, as he had made some experiments upon himself, last winter, in order to observe the sensations arising from excessive applications of the usually employed strength of the drug. "I procured a four per cent. solution, and commenced one evening at nine o'clock to make applications to the membrane in both nostrils. I used as an applicator a piece of cotton wound around a match, and endeavored to squeeze out all of the solution from the cotton, at each application. I applied the solution three times at an interval of half an hour, and then went to bed. I was rather restless and could not fall asleep as easily as usual, and I made a number of other applications at intervals of about the same time as before, until I had used up three drachms of the solution, or seven grains of cocaine. I fell asleep about one o'clock, and slept for quite half an hour, when I awoke with a start, with a feeling that my respiration was impeded and my heart slowing gradually in its action. I counted my pulse repeatedly and found it full, strong and beating a little more frequently; only I felt afraid to turn over on my left side on account of the fear I had of my heart's stopping, if I did so. I desired to get up to see the time, but, when I attempted to arise, was afraid to stand up straight for fear of the heart stopping. So assuming a creeping posture I looked at the clock and then laid down on the lounge, with my head bolstered up high, in which position, I felt less fear of impending

dissolution. At last, after standing it as long as I could, for I was fully aware all the time that I had produced the sensations myself, although I could not prevent my fear of them, I took a twenty-five grain dose of Sodium Bromide, which I had at hand, and in about half an hour fell asleep with no further disturbance. The next day, aside from feeling a little stupid on first arising, I experienced no bad after effects."

MERCURY WITH CHALK IN THE TREATMENT OF TAPE-WORM.

Dr. G. W. Squires, of East Avon, N. Y., writes that he has sometimes found mercury with chalk a most effective Tæneicide, and cites the following case in illustration: "G. W., aged thirty-one, a blacksmith by trade, had complained of an indescribable feeling in his stomach, bowels, and all through him, as he termed it, for three or four years. There was a wild look in his eyes, and a peculiar appearance of the skin which attracted people's attention so they would ask 'what ailed him?' his appetite was fastidious; at times he would eat voraciously, then again eat nothing. He became greatly emaciated, and vomiting grew so incessant that he was unable to retain any food. The vomiting had continued about six weeks when I first saw him. He had been treated by several physicians, but said he was getting worse instead of better. I gave him three powders of hydrargyrum cum crita, with directions to take one, morning, night, and morning, with a dose of castor oil after the last powder. He came back in three days surprised, smiling and happy, saying he had passed a tape-worm thirty feet long. He was no longer troubled with vomiting, ate heartily, improved rapidly, and has felt like a new man ever since the worm was expelled."

Progress of Medical Science.

Hepatic Cirrhosis in Children.—Dr. R. Palmer Howard, of Montreal, reports in the October number of *The American Journal of Medical Sciences*, two cases of this rare affection in children, in which neither the use of alcohol nor the virus of syphilis can be assigned as the cause. The author also presents a study of the clinical histories of 63 cases occurring in children before puberty, of which he has been able to collect records. As the result of this analysis he finds: 1. That most of the established causes of the disease in adults obtain also in children, more especially the use of alcohol, present in 15.8 per cent. of the whole number; syphilis, chiefly hereditary syphilis, present in 11 per cent.; tuberculous disease of other organs than the liver, in 11 per. cent.; also, but much less frequently than these, venous congestion of the liver, peritonitis, and a general tendency to connective tissue formation in the system. 2. That syphilis occasionally tends to a diffuse interstitial hepatitis or cirrhosis, by first inducing an adhesive inflammation of the portal vein. 3. That a general arterio-capillary fibrosis is not proved by these cases to be the usual, and probably not even a frequent, cause of hepatic cirrhosis in childhood. 4. That more than half of the cases of hepatic cirrhosis in children do not appear to be produced by the above mentioned well established causes of that affection. 5. That there is some evidence that cirrhosis of the liver may be very exceptionally induced by the acute infectious diseases—cholera, typhoid fever, measles, scarlatina, but that proof of this is wanting. 6. That the habitual use of a stimulating diet, or the absorption of the products of faulty digestion, are probably fruitful sources of hepatic cirrhosis in children. 7. That it is in harmony with what is known of the causes of hepatic cirrhosis to believe that the bodies known as ptomaines may be capable of exciting a cirrhotic condition, and that investigation of this subject deserves attention. 8. That the period of childhood most liable to cirrhosis of the liver is from the ninth to the fifteenth year inclusive, but that it may be congenital, and may occur at any age after birth. 9. That it is twice as frequent in male children as in females. 10. That the symptoms are essentially the same in childhood as adult life. 11. That it is frequently accompanied by pyrexia. 12. That ascites or icterus, and frequently both together, are of common occurrence in the atrophic and hypertrophic forms. 13. That the group of symptoms which have been referred to cholæmia or to cholesteræmia or to acholia, and even sometimes to uræmia, frequently ushers in the fatal issue of hepatic cirrhosis in children.

The Cardiac Relations of Chorea.—The heart symptoms of chorea demand special consideration as among the most important and peculiar features of the disease. Chorea is rarely a fatal disease in children, and hundreds of cases may be treated without a death. By far the most serious fact in the clinical history of the disease is the occurrence of endocarditis; but here the danger is remote, not immediate, and lies in the changes which an acute valvulitis may initiate. A satisfactory study of the cardiac relations of chorea must embrace the condition during the attack, and the subsequent heart history after a period of years. The first question has engaged the attention of many workers, and in the October number of *The American Journal of the Medical Sciences*, Dr. William Osler, of Philadelphia, works out the second on a scale not hitherto attempted. He has carefully reëxamined 110 of the choreic cases treated at the Infirmary for Nervous Diseases between 1876 and March, 1885, the examination in every case having been made more than two years subsequent to the attack of chorea. In 43 cases the heart was normal, in 54 there were signs of organic disease, and in 13 there was functional disturbance. A study of these cases, Dr. Osler thinks, justifies the following conclusions: 1. That in a considerable proportion of cases of chorea—much larger than has hitherto been supposed—the complicating endocarditis lays the foundation of organic heart disease. 2. In a majority of the cases the cardiac affection is dependent on rheumatism, and cannot be regarded as in any way associated with it; unless, indeed, we hold with Bouillaud, that in the disease "chez les jeunes sujets, le cœur se comporte comme une articulation." 3. As the presence of an apex systolic murmur in chorea is usually an indication of the existence of mitral valvulitis, as much care should be exercised in this condition as in the acute endocarditis of rheumatism. Rest, avoidance of excitement, and care in convalescence, may do much to limit a valvulitis, and obviate, possibly, the liability to those chronic nutritional changes in the valves wherein lies, after all, the main danger.

Hereditary Tremors.—Dr. C. L. Dana, of New York, calls attention to a peculiar hereditary motor disorder which has not heretofore been systematically described, but which he has seen, and studied in three families. The affection consists of a fine tremor, controlled for a brief time, affecting nearly all the voluntary muscles, chronic, beginning in very early life, not progressive, not shortening life, not accompanied with paralysis or any other disturbances of nervous function. It resembles to some extent the tremor of paralysis agitans, still more a simple neurasthenic tremor. A most striking clinical feature is its marked hereditary or family type, and its transmission along with other nervous diseases. It begins in infancy or childhood, sometimes being brought out by an infectious fever. It continues without progressing in severity during a lifetime, which it does not shorten. The family history will reveal neuroses or psychoses. The upper extremities are most noticeably affected, but it may involve the head, neck, eye, laryngeal, or, in fine, any of the voluntary muscles. It ceases during sleep, and can be inhibited temporarily by the will.

Everything that produces excitement or nervousness increases the tremor. It may be barely noticeable, except under some excitement, or the influence of alcohol or tobacco. It does not interfere with delicate co-ordination. It neither stops nor increases on ordinary voluntary movements; in this respect differing from the tremors of paralysis agitans, or multiple sclerosis. There may be with it slight contractures of the fingers, also developed early and non-progressive, but there are none of the forced movements, rigidity, paresis, subjective sensations, or vasomotor disturbances of paralysis agitans, while the head and neck are not so much affected, as in senile tremor. The tendon-reflexes may or may not be exaggerated. The tremor is most nearly like that occurring in neurasthenic states, or from poisons, only there is no general nerve exhaustion, and no muscular weakness. It is associated with other neuroses or psychoses, such as insanity, inebriety, and epilepsy, and also with examples of unusual talent or intellectual vigor. —*American Journal of the Medical Sciences.*

Chronic Shingles.—Besides the ordinary acute form of zona, Leudet, of Rouen, describes one which lasts months, *Archives générales de Médicine.* In it the ulcerations are very deep, or the cicatrix ulcerates afresh, and this process repeats itself several times. The ulceration may be accompanied by redness, swelling, and by a pseudo-phlegmon of neurotic origin. Finally the ulcers cicatrize, and may be replaced by keloid. This constitutes a true chronic variety of zona. Zona may also recur in the same situation, or it may extend successively to several branches of the same nerve, or of contiguous nerves. Or, lastly, the herpetic eruption spreads from one nerve to a distant one, or even to one which has no anatomical relation with the one first attacked. In addition to examples illustrating these, he cites a case where a zoster of the forehead occurred in a tubercular person who died nine months later. The histological examination showed lesions of the Gasserian ganglion, and alterations of the nerve filaments.

Hyperacid Vomiting.—Prof. Rosenthal, of Vienna, has studied this subject, which appears to be still involved in considerable obscurity. He calls attention to the fact that in certain cases of long-standing tabes, the gastric crises begin by cardialgic pains and palpitations. The vomiting that ensues may continue for days, and Rosenthal has determined that the vomited matters contain 30 to 32 per cent. of hydrochloric acid. In Rosenthal's cases, even after 15 hours' fasting, there was copious secretion of hyperacid fluids. This hyperacidity and hypersecretion were greatest at the height of the attack, and gradually declined as the latter did. This morbid excitement of the spinal centre is, therefore, in such cases, to be looked upon as the source of the abnormal gastric juice secretion and formation of hydrochloric acid. As anatomical basis of the cardialgia and vomiting in tabes, degenerations in the territory of the vagus centres have been found. Besides the typical degenerations of the posterior columns, a subependymal sclerosis attacks the posterior vagus nuclei which are found at the bottom of the fourth ventricle, which, along with the neighboring accessory and glosso pharyngeal nuclei, have been proved by Kahler and others to be subject to all grades of degeneration. Through primary irritation of those nuclear cells which are in connection with sensory fibres of the vagus, the initial cardialgia is brought about; through the farther spreading of the irritation to the functionally different ganglion cells, the vomiting is produced. The increased secretion of a fluid containing hydrochloric acid must, therefore, be brought to pass by the excitement of nuclear shells. The cardiac and pulmonary nuclei being also involved, the weakening and quickening of the heart's action, as well as the labored breathing, become intelligible. Many cases of hysterical vomiting are also to be classed with the medullary forms of hypersecretory vomiting. They are ushered in by cardialgia, and often, when the patient has fasted, great quantities of slimy fluid containing free acid are ejected. The frequent combination in such cases of a slow pulse with dyspnœa and cough point to irritation of the bulbar vagus centres. Similarly in mental overwork, the copious vomiting, the slow pulse and short breathing, must be referred to the bulb, as well as certain forms of vomiting in migraine and neurasthenia. Rosenthal thinks that he has adduced proof enough that the abnormal quantitative alteration of the stomach juices can only be caused by changes in certain nerve centres. It is not to be supposed that the vagus centres alone operate pathologically. The bulbar centres must unite in themselves the vagus elements, functionally unlike in their physiological relations. In the interest of rational treatment it is of importance to distinguish this hyperacidity and hypersecretion from acid dyspepsia. In this last it is abnormal fermentation which causes the formation of organic acids. In such a case hydrochloric acid is useful, because it energetically restrains the butyric acid fermentation. Salicylate of soda is also valuable as an antiferment. In the hyperacidity spoken of above, alkaline waters, a mixture of potash and bismuth, at times a little morphia with food, are all successful; and big doses of bromide of sodium may be given morning and evening.—*Berliner Klinische Wochenschrift.*

Hydrochlorate of Apomorphine in Dry Cough.—This drug has been extensively tried by Dr. Stocquart, of Brussels, as a remedy for certain kinds of cough, and he speaks highly of its value. The kind of cough in which it has proved most successful is a distressing and frequent hacking, unattended with expectoration, or with exceedingly difficult expectoration. The improvement of the patient's condition is usually effected in a few days. The drug is, as a rule, well borne, although a few individuals manifest a special susceptibility to its action, and rarely nausea, colic, and diarrhœa result from its employment. The dose is a minute one, only about one-twentieth grain of this alkaloid being given in water in the twenty-four hours. As the solution rapidly alters by keeping, it is advised to prevent its decomposition by the addition of a few drops of hydrochloric acid, which does not interfere with the therapeutic effects.

Odontalgia or Neuralgia.—The great difficulty occasionally experienced in diagnosing whether neuralgic pain of the fifth nerve is due to peripheral irritation from disease of the teeth or to some affection of the nerve trunk, made Professor Victor Horsley's paper on this subject at the Odontological Society of considerable interest, especially to dental surgeons. The principal points of distinction may be summed up under the following heads (*The Lancet*): 1. Trophic changes, such as muscular wasting in the parts to which the pain is referred, chronic congestion, or alternating dilatation and constriction of the blood-vessels, point to mischief in the trunk of the nerve. 2. Alterations in sensation, anæsthesia or hyperæsthesia of the skin, especially when gently touching the skin causes extreme pain, while firm pressure causes no pain at all, are, he believes, never due to dental irritation. 3. The origin and character of the pain are sometimes useful as a means of diagnosing the two conditions. When the pain begins in the skin or bone, and, subsequently, is referred to the teeth, the probability is that the lesion is in the nerve trunk; if it is stated to begin in the teeth, it may or may not be due to them. Professor Horsley expressed the view that *constant* pain is in most cases of peripheral origin, whereas intermittent pain is due to trouble nearer the nerve centre; but this is opposed to the experience of most dental surgeons, intermittent pain being a frequent accompaniment of dental disease. Lastly, the existence of "tender spots" along the course of the nerve or its branches is generally an indication of irritation along the whole course of the nerve, but occasionally occurs in cases of peripheral irritation.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, October 29, 1887.

THE SALIVA AND THE GASTRIC JUICE.

THE importance of mastication in the economy of chylopoëtics has always been admitted, but the value of the saliva except as a solvent and lubricator, has been much doubted. Most of the early physiologists, including Schwann, Beaumont and Claude Bernard, thought that saliva had no more value in digestion than pure water. In later years, however, the experiments and observations of Frerichs, Brücke, and especially Von den Velden have shown that saliva has a practically useful rôle as a starch digester. Clinical observers have noticed severe digestive and nutritional disturbance resulting from loss or deficient secretion of saliva. Frerichs found the symptoms to be anorexia, and a constant sense of pressure in the epigastrium. Wright collected in a week a quart of saliva from his own glands, and during that time lost twelve pounds in body weight. The same observer found that food injected into the stomach of dogs digested imperfectly when saliva was kept from the stomach by ligating the œsophagus.

The generally accepted view is now that which was first solidly established by Von den Velden: viz., that the saliva after being taken into the stomach with the food acts for a time upon starchy matters, turning them into glucon. After ten or twenty minutes, the acidity of the gastric juice has so increased as to stop the amylolytic action, and only proteid digestion begins. Dr. George Sticker, who, in conjunction with Dr. Curt Hübner, has made some experimental studies on the physiology of secretions (*Leitich, f. Klin., Wed. Bd.* XII hft. 1 n. z. 1887) has recently published an article (*Klinischer Vorträge* No. 297) in which still more is claimed for the saliva than a purely amylolytic power. He believes that this secretion taken into the stomach assists in the formation and secretion of pepsin, and thus indirectly assists in proteid digestion. A suspension of salivary secretion suspends largely that of peptic secretion also. He cites the case of a woman who suffered from an almost complete suspension of the salivary function.

There was indigestion of meats as well as of carbohydrates. The re-establishment of the salivary flow by means of infusion of jaborandi, relieved the stomach trouble also. Sticker performed several curious experiments to test the capacity of the stomach to digest food without the help of saliva. In one case, after twelve hours' fast, the person experimented upon had his stomach carefully washed out, and was then given the whites of four eggs. The saliva was then expectorated or carefully absorbed by a sponge placed in the mouth. After two hours the stomach contents were carefully removed, and the egg-albumen was found to be only slightly digested. The gastric juice was tested, and found to be weak in proteolytic power and in acid. In the central experiment the albumen was found digested, and the gastric juice fully up to the normal in acidity (.25 per cent. HCl), and peptic power. Four experiments of the kind indicated were performed, and all leading to the same result. The view of Sticker includes more than the commonly accepted opinion that the alkaline saliva stimulates the flow of gastric juice. He believes that saliva actually assists in the complex process by which the active constitutents of the gastric juice are formed. His work, at any rate, will emphasize the practical importance of the thorough mastication and insalivation of food. The victims of the gum-chewing habit will find some physiological justification in Sticker's "Wechselbeziehungen Zwischen Speichel und Magensaft."

THE PROGRESS OF PNEUMOTOMY.

WE have been at some pains to keep our readers informed regarding the progress of pneumotomy and of thoracic surgery in general.

As is well-known, the abdominal cavity has had to yield to modern science, and the peritoneum with the organs it envelops has become but a plaything to the expert laparotomist. The cranial cavity is also being successfully invaded; but as yet no great progress has been made in dealing surgically with affections of the lung.

Dr. G. Foubert (*Archives general de Medicine*, October, 1887,) has recently collected the cases of pneumotomy so far reported, and analyzed them, with somewhat instructive results. The total number of cases is eighty, with forty-seven cures and thirty-three deaths. As will be seen by the record given below, however, the high percentage of cures is due to the hydatid cases, in which the operation is often very simple.

The success, however, with gangrenous cavities, and in bronchiectasis and abscess, is fairly good if the reports indicate in any measure the true proportions. The summary is as follows:

1. Tuberculous cavities, in which there was incision made either with or without a resection of the rib, seven cases. In one, that of John Hastings, recovery is said to have occurred; in another case, the patient lived for some time; in the remainder, the patients died.

2. Abscess of the lung, fourteen cases, with nine cures and five deaths. In two of the fatal cases, death could not be attributed to the operation.

3. Hydatids of the lung and pleura, thirty-four cases with twenty-nine cures. Probably in some of these cases the hydatids were pleural. These figures relating to the hydatids were collected for the most part by Dr. J. Davie Thomas, and it is noticeable that the most of them (twenty-five) refer to Australia. Only one, pneumotomy, for hydatids, had been reported in American literature up to 1885.

4. Gangrene of the lungs, eighteen cases, with nine cures; two ameliorations and seven deaths.

5. Bronchiectasis, twelve cases, with four cures.

The above figures require little comment. They show fairly good results for pneumotomy in gangrene, abscess, and hydatids; but for tuberculous disease surgery has as yet done nothing.

THE CHOLERA SCARE.

An opportunity has been offered to the secular press within the past few days for discussing the probability of Cholera becoming epidemic in this city. From the present outlook, however, the argumental pyramid, from the sensational standpoint, has been, as usual wrong side up. While it is always proper to be on the alert against possible danger, there is no necessity for any alarm. It is well known that the Cholera germ is distributed primarily by the evacuations of persons affected with the disease; and, secondarily, by contaminated clothing, utensils, food and water; that no amount of filth, heat or moisture will propagate the disease without the presence of the specific poison; that the disease is not contagious in the sense of being communicable by contact, and that an intelligent quarantine, vigorous sanitary measures and thorough sequestration will serve to stamp out even an epidemic of the disease. Although the quarantine regulations are not as strict for this port as they might be, to prove that quarantine as such is worth anything, we have still the comforting assurance that under the pressure of medical and lay opinion all the other necessary precautions are being taken to prevent the spread of the malady. And these latter give the only guarantee of safety, quarantine being only one of the means to such an end. The suggestion regarding the improvement of the quarantine buildings for the better accommodation of patients is a very proper one, and needs only to be acted upon by our next legislature to make assurance doubly sure against the possibility of the spread of the disease at any future time.

ABUSE OF MEDICAL CHARITY.

The *Evening Telegram* and the *Standard* have been agitating the Medical Charity question with a great deal of spirit. It is a trite story, but repetition may yet bring about reform. The public hardly needs to be told that the physicians of dispensaries and hospitals are grossly imposed upon. The evil is increasing every year. The people are not so much to blame as at first appears. There are too many doctors who are thirsty for clinical material, and coax their consciences for interesting cases. Besides the managers wish to pose as great philanthropists, and there are too many of such angels who carry their charitable trumpets under their wings. So the multiplying dispensaries must have custom, and the young doctors must be without it.

THE ABANDONMENT OF QUARANTINE.

England's commercial interests have always led her to doubt the need and distrust the efficacy of quarantine. She has held what she is pleased to consider the "common-sense view," viz., that though theoretically quarantine may succeed in keeping out disease, practically, in any large country, it amounts simply to an irrational derangement of commerce." England has long since, says the *British Medical Journal*, discarded quarantine as a means of preventing cholera, and now places her trust in the security afforded by purity of local surroundings—of soil, air, and water—on land; and a system of watchful medical inspection of shipping at her seaports. The success of this policy, continues our contemporary, has been complete, and there are not wanting indications that this success is exercising a beneficial effect on public opinion abroad. It is added that at the recent International Hygienic Congress, at Vienna, opinion seemed to be turning against quarantine. Italy and Austria, in particular, are wavering in their allegiance to the older methods.

News of the Week.

The Yellow Fever at Tampa, Fla., at last accounts was not abating. On October 21st, there were thirteen new cases and three deaths reported.

Two Cases of Small-Pox have appeared in Brooklyn.

Typhoid and Malarial fevers are reported to be unusually prevalent in Cincinnati, and the cause is believed to be the drinking water.

The Hospital for Contagious Diseases of Richmond County, Staten Island, is reported to be badly constructed and badly managed in every way.

The Crown Prince.—The *Independence Belge* of Brussels, publishes a letter from Dr. Sigismunde, a prominent American, and a friend of Dr. Mackenzie, correcting the popular errors regarding Crown Prince Frederick William's health. In the letter, Dr. Sigismunde states that the Crown Prince's voice would have been lost forever if he had been treated by the German physicians.

The International Medical and Surgical Synopsis is the title of a new journal published monthly in St. Louis, and edited anonymously.

Medical Society of the County of New York.—At the Eighty-second Annual Meeting, held October 24th, 1887, the following officers were elected for the ensuing year; *President*, Laurence Johnson; *Vice-President*, L. Bolton Bangs; *Secretary*, Wesley M. Carpenter; *Assistant Secretary*, Charles H. Avery; *Treasurer*, Alexander S. Hunter; *Censors*, Daniel Lewis, John S. Warren, R. Van Santvoord, Wm. E. Bullard and Wm. Stevens. At the conclusion of the Treasurer's report, the following resolution was unanimously adopted:

Resolved, That this Society hereby returns its most sincere thanks to Dr. Orlando B. Douglas, its retiring treasurer, and extends to him its high appreciation of the faithful manner in which he has discharged the duties of his office.

The Report of Dr. Daniel Lewis, appointed by the *Comitia Minora* to superintend the publication of The Medical Directory, showed that the book had been published with a balance in favor of the treasury of the Society. A vote of thanks was given to Dr. Lewis for the efficient manner in which the work had been performed. The Society ordered the publication of the Directory to be continued, and referred its publication to the *Comitia Minora* with power.

The Report of the Board of Censors, read by Dr. Wm. E. Bullard, Secretary, showed that the work of prose-

cuting illegally qualified practitioners in the City of New York had been vigorously and efficiently pushed by the Counsel of the Society, W. A. Purrington, Esq. The new law will enable the Society to do its work in this direction with greater facility and rigor than heretofore.

The Report of the Committee on Hygiene included a special report on *Cholera at Quarantine*, made by Dr. John C. Peters, in which it appeared that the buildings upon Hoffman and Swinburne islands, in the lower bay, while dingy, are remarkably clean, that no new cases have developed recently, and that the danger of the disease spreading had probably passed. In the opinion of the reader of the report, the law should be amended so that $5,000 yearly be expended annually from the fees of the Health Officer of the port in keeping the quarantine buildings in the lower bay in proper condition, to meet promptly the invasion of infectious and contagious diseases. He thought that Philadelphia had stolen a march on New York in making microscopical and biological investigations of cholera in the port of New York. The report gave rise to some discussion, which was participated in by Dr. Daniel Lewis, the President, and Dr. Peters.

It was voted that the *Annual Dues* for the ensuing year be *three dollars*. After the transaction of other routine business, the Society adjourned to meet on the fourth Monday in November at 8. P. M.

Football Mortality.—A student in the seminary at Cazenovia, N. Y., while playing football, accidentally collided with another student. The concussion is thought to have produced the rupture of a blood vessel. At any rate the victim died in twenty-four hours.

The Connecticut Hospital has received a gift of $7,000, from Mrs. Henry Farnum, for the purpose of erecting an operating pavilion.

Dr. Francis J. Quinlan, of this city, has been appointed Instructor in the Department of Diseases of Throat and Nose in the New York Polyclinic. Dr. Quinlan has been associated with the Polyclinic for nearly three years. He likewise holds positions in the New York Eye and Ear Infirmary, Northern Dispensary, and is the assistant of Prof. Lefferts at the College of Physicians and Surgeons of this city.

American Public Health Association.—The fifteenth annual meeting of this Association will be held at Memphis, Tenn., Tuesday, Wednesday, Thursday, and Friday, November 8, 9, 10 and 11, at Young Men's Hebrew Hall. The West Shore Railroad has established a special rate for members from New York; $37.20 being charged for the round trip.

Gynecological and Obstetrical Society, Baltimore, Md.—At the meeting of the Gynecological and Obstetrical Society, of Baltimore City, held on October, 11th inst., the following officers were elected: President—Dr. H. C. P. Wilson; First Vice-President—F. E. Chatard, Jr., M.D.; Second Vice-President—John Morris, M.D.; Secretary—Chas. O'Donovan, Jr., M.D.; Treasurer—Robt. T. Wilson, M.D.

New York Post-Graduate Medical School and Hospital.—The following new appointments have been made by the Directors of this Institution: Dr. Robert Abbe, Professor of Clinical Surgery: Dr. A. M. Phelps, Professor of Orthopedic Surgery; Dr. Henry D. Chapin, Professor of Diseases of Children; Dr. J. H. Girdner, Instructor in Clinical Surgery.

The late Dr. Joseph C. Hutchison.—At the regular meeting of the Board of Regents, held this day in the rooms of the Long Island College Hospital, Brooklyn, N. Y., the following proceedings took place, and were entered on the minutes:

The members of the Board, having learned with unfeigned sorrow and regret of the death of Joseph C. Hutchison, M.D., President of the Collegiate Department, are deeply impressed with the great loss the Institution under their care has sustained by being deprived of his counsel and aid. Dr. Hutchison was an industrious worker, an eminent surgeon, and a good citizen. He was a thorough scholar, and a successful teacher; he was highly esteemed by his professional brethren, and was loved and respected by all who knew him. He brought to the advancement of the interests of the College a mature mind, a ripe judgment, and a steady, faithful and sincere application, that promised much for the future, thus fulfilling the highest hopes of his fitness for the place he occupied. On motion it was

Resolved, That a copy of the foregoing minutes be signed by the President and Secretary, and sent to the family of Dr. Hutchison, and that copies be also supplied to the press for publication.

Thomas H. Rodman, *President.*
Wm. T. Osborne, *Secretary.*

Dr. Edwin Hutchinson, of Utica, one of the leading physicians and ophthalmologists of New York State, died on October 19th, aged 47 years, after a long illness.

The Percentage of Sterility Among Men.—Kehrer, of Heidelberg, has examined 96 men, as follows: Impotent, 3; having semen containing dead spermatozoa, 29; deficient spermatozoa, 11; excessive spermatic secretion, 53. The percentage of sterility is thus 33.32. —*Wiener Presse*, July 10, 1887.—*Med. News.*

A Cause for Diphtheria.—There is considerable diphtheria in various parts of New Jersey, and the Secretary of the State Board of Health, Dr. Hunt, thinks it is largely due to damp cellars which are suddenly heated in the Fall. This theory has been verified for several years by reports from various places where the disease has raged. It is claimed that during the summer in many cellars a good deal of vegetable matter is allowed to decay, and when the fires are started in the fall this decayed matter is stirred up and mingled with a peculiar dampness which must be in the cellar, and it pervades the entire house.

Colleges in Good Standing.—At the quarterly meeting of the Illinois State Board of Health, held July 8, 1887, the following resolution, offered by Dr. Clark, of the board, was adopted: *Resolved*, That the phrase, "medical colleges in good standing," in the first section of the Act to Regulate the Practice of Medicine, approved June 16, 1887, is hereby defined to include only those colleges which shall, after the sessions of 1890–91, require four years of professional study, including any time spent with a preceptor, and three regular courses of lec-

tures, as conditions of graduation, and shall otherwise conform to the Schedule of Minimum Requirements heretofore adopted by the board.

Homœopathy and the Cook County Hospital.—Dr. M. J. Bliem, of Chicago, ex-*interne* of the Cook County Hospital, writes us with reference to the respective mortality rates among patients on the regular and homœopathic departments of the Hospital. This (the lower rate in the homœopathic side) can not, he says, be due to any difference in the character of the cases, because the examining physician sends every fourth surgical and every fifth medical case to the homœopathic wards, and no other distinction is made. Our correspondent, however, appears to have a very childlike faith in the Rhadamanthine justice and discretion of the examining physicians, who, he admits, are regulars. It is most likely, we fear, that a perhaps unconscious bias produces a selection of the more interesting and, as a rule more old cases for treatment by rational medicine.

Owing to stress of competition abroad, many physicians in Germany will make a professional visit for half a mark (about 10 cents), and Prof. Hegar has said that unless something is done to put a stop to the present rush of men into medicine, the profession will become "a veritable *proletariat*."

A case of Thoracic Aneurism, cured by external application of the strong galvanic current is reported by Dr. S. Balp, in *Revista Clinica*, June, 1887. The applications were made daily for several months.

Bequest to a Medical College.—Mr. Richard Quain, F.R.C.S., F.R.S., has bequeathed almost the whole of his fortune, amounting to about £75,000, to University College, London, subject to certain annuities to family connections. The College will, we are informed, at once benefit to the extent of £60,000, which sum is left to four trustees, to apply the annual income in "the promotion and encouragement in connection with University College, London, of general education in modern languages (especially the English language and composition in that language, and in natural science."

Another Cure for Sea-Sickness.—Dr. W. W. Skinner, late a ship surgeon of considerable experience, is convinced that he has discovered remedies which cure sea-sickness.—*British Medical Journal.* These are atropine, strychnine, and caffeine; the two former are administered simultaneously, the latter alone. Sea-sickness may be cured either by atropine associated with strychnine, or by caffeine held in concentrated solution by salicylate or benzoate of sodium. These substances are all administered hypodermically. This mode of administration was chosen for the following reasons: the frequent vomiting in naupathia, by which the agents employed would be lost; the difficulty of their absorption from the stomach in this affection; and also the retaining and destructive action of the liver upon these alkaloids when absorbed from the gastro-intestinal tract (Heger, Schiff, Lantenbach, and others). The dose of atropine and strychnine for adults is 1 milligramme of each. It would, perhaps, be better to give a little less of atropine, and the double or triple of strychnine. The following, however, is the formula employed: Atropinæ sulph., strychninæ sulph., ãã 0.04 gramme; aq. menthæ, 40 grammes. One gramme o this solution contains 1 milligramme of each of the alkaloid salts. In warm climates the solution must be frequently renewed. If after two hours the patient is not cured, a second injection of one gramme of the mixture may be given, but it would be imprudent to repeat this dose of atropine too frequently. The following is the formula employed in administering caffeine to adults: Caffeine, 4 grammes; sodii salicyl., 3 grammes; aq. destill., q. s. ad 10 cubic centimètres. Dissolve by gently heating. Each cubic centimètre contains 0.40 of a gramme of caffeine. A single hypodermic injection of 0.30 of a gramme of caffeine completely cured in seven hours a patient who had been suffering intensely from sea-sickness during three days. Another patient was cured in five hours. Certain disadvantages of the method exist, but are not of great importance. Dryness of the throat is sometimes caused by the atropine, and young children may present an intense redness of the skin; amblyopia caused by this alkaloid is occasionally observed in adults.

Atropia was recommended for sea-sickness by Dr. Beard in 1880.

Massachusetts and Habitual Criminals.—Massachusetts has followed the example of Connecticut in dealing with habitual criminals. By a law passed by the last Legislature any criminal convicted of a State prison offence, who has previously served two terms of more than three years each, must be sentenced to twenty-five years' imprisonment. This means practically that habitual criminals are to be sequestered for life. It is a wise provision, based both on science and on sense.

Obituary.

JAMES KNIGHT, M.D.,

NEW YORK.

Dr. James Knight, Surgeon-in-Chief of the Hospital for the Relief of the Ruptured and Crippled in this city, is dead. Dr. Knight was born at Taneytown, Frederick county, Maryland, on Feb. 14, 1810. He was the son of Samuel Knight, a manufacturer of military implements, and graduated from the Washington Medical College, Baltimore, in March, 1832. From 1842 to 1844 he assisted in the orthopedic treatment of patients, attending the public clinics of the Medical Department of the University of the City of New York. The formation of the New York Society for the Relief of the Ruptured and Crippled was due to his endeavors, and has been under his direction since its start. In 1870 the Society erected the building at Forty-second street and Lexington avenue. Dr. Knight was a member of the Medico-Chirurgical Faculty of Maryland, the District Medical Society of Ohio, the County Medical Society of the City of New York, the Medical Journal Association of the City of New York, President Fellow of the New York Academy of Medicine, a life member of the New York Society for the Relief of Widows and Orphans of Medical Men, and also of the American Museum of Natural History, an honorary member of the New York Historical Society, and a Fellow of the Academy of Design. He published a work on "The Improvement of the Health of Children and Adults by Natural Means" in 1868, and one entitled "Orthopedia, or a Practical Treatise on the Aberration of the Human Form," in 1874.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 20, 1887.

A. JACOBI, M.D., PRESIDENT, IN THE CHAIR.

THE CORRESPONDING SECRETARY reported the receipt of valuable volumes on Dermatology and Syphilis, donated by Mr. Berman Cushman, from the library of his son, the late Dr. Joseph Cushman. The books had been placed in the Library, and the thanks of the Academy would be returned to the donor by the Librarian.

THE STATISTICAL SECRETARY reported the deaths of Dr. Woolsey Johnson, and Dr. Morris Leo Wolf, one of the founders of the Academy.

THE PRESIDENT acknowledged the receipt of several *Autograph Letters*, and again spoke of the value of similar contributions to the Library.

DR. CLINTON WAGNER then read a paper on

COLORADO SPRINGS AND DAVOS-PLATZ, AS WINTER HEALTH RESORTS,

in which he fully described each place, and compared the two. The comparison was very favorable to Colorado Springs, and the paper was an endorsement of the view that the conditions most favorable to exert a curative influence on phthisis pulmonalis could be found at high altitudes. His conclusions were based upon personal observations as a resident in the two places named.

He believed that cases of laryngeal phthisis could be allowed to remain at high altitudes, provided that improvement in the pulmonary phthisis and general condition had already taken place.

Davos-Platz is an Alpine valley, and probably one of the best drained towns in Europe. The drainage of Colorado Springs, at present, is not especially commendable.

DR. A. L. LOOMIS said that Dr. Wagner's paper had brought up some of the most interesting points in connection with the climatic treatment of pulmonary phthisis, whose hold upon the profession was becoming stronger and stronger. The point of special interest was that of the climatology of high altitudes. Not having had time to carefully prepare a paper, such as the subject was worthy of, he would simply give some of the results of his own observations and the impressions which he had derived from them. Several years ago he read a paper on the Climatic Treatment of Phthisis before the American Medical Association, in which he took the ground that the custom of sending phthisical patients to a warm climate was wrong, because the most important factor was a stimulating atmosphere which would enable the patients to take regular exercise in the open air. Since that time his study of the climatic treatment of phthisis had led him to believe that there was no single locality which was preferable to all others, but that there were

TWO ELEMENTS WHICH ARE ABSOLUTELY ESSENTIAL

if the atmosphere of any locality is to exert a curative influence in this disease.

First, the air must be pure, aseptic if you choose, which could be taken into the lungs, on the same principle that antiseptics were used externally in the treatment of surgical affections. Cavities in the lungs could not be washed out with antiseptic solutions, and he doubted whether such solutions could be applied by inhalations, so as to destroy the cause of the morbid processes going on in the lungs. But if the lungs could be bathed constantly with aseptic air, all was done that could be in the way of local treatment of pulmonary phthisis.

As a rule, the atmosphere at a high altitude was aseptic, when unaffected by conditions of soil, foliage, and the aggregation of human beings. Doubtless the air of Colorado Springs and Davos had been aseptic, but probably as soon as these localities become thickly populated, it would no longer remain aseptic, and they would be abandoned as health resorts for this class of patients. That the air of high altitudes was curative, he did not believe, nor was an equable climate.

Second, the atmospheric conditions must be such as favor spending most of the daytime out of doors. If patients were not able to be out of doors, they were not in a condition to be sent to a health resort. That was the prominent reason why patients in the first stage of phthisis were benefitted by climatic change, whereas the life of patients with cavities in their lungs was generally shortened by these changes.

Pure air could be found in other localities than Colorado and Davos, but between these two, the increased amount of sunshine made the former preferable to the latter. But there was an objection to sending patients to either of these places, namely: if they did not remain there for two or three years after recovery was complete, the disease was almost sure to redevelop within one or two years. When, however, they were sent to regions where pure air could be obtained at a lower altitude, the recovery when obtained, was more likely to be permanent.

DR. R. P. LINCOLN wished only to emphasize a few of the points which had been brought out by Dr. Wagner, some of which had been referred to by Dr. Loomis. He had watched patients who had lived in these localities, and believed that the advantages offered by Colorado were superior to those of Davos. The larger amount of sunshine in Colorado was decidedly in its favor when compared with Davos, the day being—from sunrise to sunset—nine hours long in Colorado, against five hours at Davos. There was also less moisture at Colorado than at Davos, and the soil of Colorado favored dryness. Cloudy days in Colorado were very infrequent.

As to laryngeal phthisis being benefitted by going to the mountains, there had been a change of opinion on that point within a few years, as some of these patients did very well in high altitudes.

DR. BEVERLEY ROBINSON sent a letter which was read by the Secretary. In it he urged the importance of aseptic air in the treatment of pulmonary phthisis, and expressed the hope that Colorado Springs would prove to be the beneficial winter health resort which it promised to be.

DR. KRETZSCHMAR said that Hermann Brehmer, in 1852, first directed attention to the curability of phthisis pulmonalis in high altitudes. According to Brehmer's statistics the aseptic air of high altitudes did not become contaminated by increase of population, as in Görbersdorf the rate of mortality had diminished rather than increased, although the number of phthisical patients there annually had increased by many thousands.

The conditions which made any locality most beneficial were the following, but it must not be expected that all of them could be found in one place. Any place that came nearest to including them all, should be regarded as

THAT OFFERING THE GREATEST ADVANTAGES

for the cure of phthisis pulmonalis.

Elevation and immunity from phthisis. Absence of moisture. Sunshine. Absence of fogs, of rapid changes of temperature, and of dust. Accessibility and distance from large cities. Constant supervision of an intelligent physician. Best of nourishment. Moderate use of wines. Perfect hygienic arrangement of dwellings.

One objection to Davos was the admixture of pleasure seekers and patients, much to the detriment of the latter. The dust of Colorado Springs also was objectionable.

Patients with cavities in their lungs, or with phthisis complicated with emphysema, cardiac disease, or Bright's disease, and patients with irritable nervous temperament, should not go to Davos. As a prophylactic, he believed Davos to be almost the ideal.

The President said that when comparison was made between the reports of physicians and travelers concerning any health-resort, considerable difference would be found to exist. As a rule, the reports of resident physicians were rather overdrawn. These and many other factors must be taken into account in estimating the value of any health-resort. When Dr. Noeggerath returned from Davos, a few years ago, almost no words he could use expressed his contempt for the place; it was the most unhealthy locality a man could live in; there was not a decent water-closet in the whole place, etc. Improvements doubtless have been made, but in all places improvements were apt to be followed by retrogression.

There were, doubtless, places of immunity in the high altitudes of Germany and Switzerland. But, on the other hand, there were facts which showed that the immunity was only apparent, because phthisis was abundant in other localities with an equal elevation.

It was, therefore, not altitude nor immunity alone that was to effect cure in phthisis, but cure involved to a very great extent mode of living. All agreed that certain hygienic and atmospheric conditions must be present, in order that any locality might be beneficial. One of these elements had not been mentioned—namely—ozone, which seemed to exert a favorable influence in these cases, and ozone was produced by sunlight. But it could also be obtained in localities other than those of high altitude. Some phthisical patients did well at sea.

Dr. Loomis had no doubt that the air of Colorado was aseptic, but he doubted if if could remain so without the antiseptic emanations developed in the locality, as from evergreen forests, etc. In the lack of these natural antiseptic agencies the air might be rendered impure by emanations from the soil, etc.

Dr. Westerbrook asked concerning the character of the laryngeal phthisis mentioned by Dr. Wagner.

Dr. Wagner said that his experience in laryngeal phthisis in Colorado was limited, having seen only two cases. There was thickening and infiltration of the epiglottis in one case, and in the other the usual appearances were well-marked.

He saw no reason why patients who could not take exercise in the open air, should not go to Colorado, for they could lie in a hammock in the sunshine, and after a time be able to ride and walk, as was the case with a member of his own family.

In Davos, however, they must take exercise to keep warm when out of doors.

The President remarked that Brehmer claimed that the air in all his rooms at Görbersdorf was changed completely three times an hour.

The Academy voted to establish a Section on Diseases of Children, after which it adjourned.

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Sixteenth Annual Session, held in Toulouse, September 22 to 29, 1887.

(Special Report to The Medical Record.)

Thursday, September 22nd—First Day.

The first session of the Association was held in the hall of the Théâtre du Capitole, under the presidency of Dr. Rochard.

AN ADDRESS OF WELCOME

was delivered by the Mayor of Toulouse, who extended a cordial greeting to the members and guests, the latter coming from all parts of Europe and even from "marvelous America."

THE ADDRESS OF THE PRESIDENT

was then delivered by Dr. Rochard, the title of the address being

THE FUTURE OF HYGIENE.

The speaker deplored the fact that the science of hygiene was even yet regarded as of so little importance, and that its teachings received so little encouragement in the way of money grants from the state. Yet in spite of the many drawbacks, the study of hygiene was making good progress in France, and the orator predicted a brilliant future for this young science.

Dr. Schlumberger, the secretary general, then read an

HISTORICAL SKETCH

of the work of the Association, in its various branches, during the year just past. Other reports were presented by the different officers, and the general session was then adjourned, the members repairing to the places of meeting of the different sections.

Friday, September 23rd—Second Day.

A communication was received from Dr. E. Brémont, upon the

EUTROPHIC ACTION OF THE TURPENTINES

in chronic catarrhal affections of the respiratory passages. He employed the substances in the form of inhalations. The effect was an almost immediate improvement in the general nutrition. It was chiefly in non-tubercular troubles that these effects were obtained.

Dr. Carre, of Avignon, reported a case of

LAPAROTOMY IN TUBERCULAR PERITONITIS.

The patient had had ascites, for the relief of which she had been tapped. Following this there had been gradually increasing obstruction of the bowels, until finally an obstipation lasting two weeks led to the adoption of radical measures. When the abdomen was opened it was found that the intestine, at the junction of the ascending transverse portions of the colon, was strangulated by an omental band. It was found impossible to free the intestines, and an artificial anus was made. There was no trouble on the side of the peritoneum, but the operation seemed to light up pulmonary disease, for the patient died within two weeks of acute phthisis. The speaker did not think that this operation was contra-indicated in cases of tubercular peritonitis.

Dr. Andre, of Toulouse, reported a curious case of

CHROMIDROSIS.

The patient, a man 22 years old, presented a pinkish exudation on the two wrists and under the nails. Examination of this exudation showed it to consist of little pink granules mingled with epithelial cells. The patient presented no hysterical symptoms.

Dr. Arnaud then read a paper entitled

THE SIGNS OF DEATH.

The speaker seemed to believe that life might still be present even when all the usual signs of it were absent. He said it was not sufficient to determine whether the respiratory and circulatory organs were in a state of action, but it was necessary to ascertain whether or not they had actually lost their power of being revived.

Dr. Thirair reported a case of

SARCOMATOUS DEGENERATION OF THE TESTICLE.

The diseased organ was one which had been retained in the abdominal cavity, and was removed by laparotomy. Although it had been necessary to make a large incision in the bladder, the patient nevertheless made an excellent recovery. In view of the frequency with which a retained testicle becomes the seat of some form of new growth, the speaker suggested the propriety of early castration in such cases as justifiable prophylactic measure.

M. Gosse then read a paper on

DEATH BY HANGING,

in which he related some experiments performed upon himself. They were not as complete, however, as he would have liked, for on one occasion he had lost conscious-

ness, and his wife then vetoed any further experiments of the kind.

Dr. Duplouy then read a paper on

AMPUTATION AT THE KNEE JOINT,

in which he took the ground that the prejudice against this operation was in great measure unjust. He showed a patient whose leg he had removed at the knee joint sixteen years before. There was a good stump, and the man was able to walk many miles every day without the slightest discomfort. Out of sixteen cases of knee-joint amputation performed by French surgeons, ten had a perfect stump, five were not able to bear their weight on the stump, and one had died. He thought that, whenever the soft parts were healthy, it was far perferable to disarticulate at the knee than to amputate either through or above the condyles.

In the discussion following the reading of this paper, M. Pamard and Maréchal reported three more cases, one successful and two resulting in the death of the patients.

Dr. Monod reported three cases of

ABORTION INDUCED BY KRAUS' METHOD.

which consists in the introduction of an ordinary elastic sound, leaving it in position until it is expelled along with the ovum by the uterine contractions. The operation was necessitated by narrowness of the pelvis. All the cases recovered. Antiseptic precautions were observed in every instance.

Dr. Jeannel reported a case of

TUBERCULAR PYO-SALPINGITIS,

which had been mistaken for an ovarian cyst. It was removed by operation. The patient subsequently died of a tubercular pelvic abscess. The speaker referred to the difficulty of making a correct diagnosis in such cases.

Saturday, September 24th—Third Day.

Dr. Bergeon contributed a paper on his method of treating phthisis by

GASEOUS ENEMATA.

The speaker referred to his later experiments, the results of which, he said, only confirmed the belief which he entertained concerning the utility of the method. He now made use of a simplified apparatus. He insisted that those who made a trial of this method should follow strictly his directions in every respect; for if they did not it would be unfair to attribute their failures to imperfections in the method. He expressed his gratification at the numerous trials of his procedure which had been made, especially by American physicians.

Dr. André related two cases of

ANEURISM OF THE AORTA,

treated by sodium iodide. The first case resulted in a cure, and the second, one of multiple aneurism, was so greatly benefitted as to be practically cured.

Dr. Moure read a paper on the

VOCAL TROUBLES ASSOCIATED WITH LARYNGITIS.

He endeavored to prove that these were caused more by paresis or paralysis of the laryngeal muscles than they were by changes in the mucous membrane. The muscles chiefly affected were the arytenoid and the thyro-arytenoid.

Dr. Stoeber read a paper in which he discussed the

CONVERGENCE OF THE EYES,

caused by the necessities of binocular vision, and explained the mode of measuring the degree of convergence by means of Landolt's opthhalmodynamometer.

Dr. Gillet presented a communication on two rare forms of

KERATITIS.

The first form consisted of numerous minute sub-epithelial abscesses, which produced an appearance of little stars. This stage was, however, so evanescent that it had hitherto escaped observation. The second form, which he called "trabecular," was due to the infiltration of lymphatic cells into the corneal tubes, giving them the appearance of little needles. This form might be primary or secondary, occurring with special frequency after keratotomy.

Dr. Burot related a case of

ECHOLALIA AND COPROLALIA

combined with motor inco-ordination. The patient was a girl, 19 years old, very intelligent and of good social position, who suffered from convulsive attacks involving the face and upper extremities. At these times she would give utterance to inarticulate cries and obscene words. She also imitated all noises and gestures which were made in her presence. When not suffering from these attacks she was very nervous, starting at the least sound. She also seemed to be incapable of doing what she wished, and when she commenced any action would often be compelled to do just the opposite. Hypnotism had been tried in this case, but it had been found impossible to induce that state. The speaker had then tried the effect of persuasion, telling the patient that she had the power to do what she willed if she would only exert it, and urging her to be calm and to trust to herself. She was now greatly improved, and he had every reason to hope that a definite cure would eventually be obtained.

Dr. Duplouy reported a curious case of what might be called

CONVULSIVE BARKING,

occurring in the person of a young officer. The patient would throw his arm quickly forward by an involuntary movement, at the same time having a convulsive movement of the pharyngeal muscles by which air was expelled with a barking sound. These attacks occurred most frequently when the young officer was about to address one of his superiors, and the latter would be astonished to receive a blow and hear a bark or some unseemly words proceeding from the mouth of his subordinate. The patient improved gradually as he advanced in years.

Dr. Grasset followed with a communication upon the significance of

JERKING INSPIRATION

synchronous with the movements of the heart. The jerking inspiration is heard usually along the left border of the sternum in the second and third intercostal spaces, and is sometimes accompanied by two faint systolic murmurs heard at the end of expiration. The inspiratory sound is broken by three distinct jerks. The speaker did not regard this sign as necessarily indicating either tuberculosis or cardiac trouble. He believed that it was a pulmonary sound indicative of respiratory weakness.

Dr. Gross, of Nancy, then read a paper on the

TREATMENT OF HYDROCELE.

He sought to differentiate between the various forms of this affection, laying down rules for the treatment of each. He favored antiseptic incision of the sack in cases of congenital hydrocele, in cases of relapse and in those which had proved rebellious to other methods, in a very large or a multilocular hydrocele, and when the tunica vaginalis was thickened. In cases of simple hydrocele of moderate size he had recourse to injections of iodine.

Dr. Régis presented a communication on

DUPUYTREN'S CONTRACTION

of the palmar aponeurosis, in which he accepted the views of those who regard this affection as one of a gouty

nature rather than as a consequence of traumatism. He related a case of this contraction occurring in a patient with general paralysis, which he thought was confirmatory of this theory.

Dr. Mossé read a paper on the use of

COLD IN THE TREATMENT OF CHOLERA,

especially during the algid stage. His plan was to rub the patient with ice, giving him at the same time rum ice internally, and hypodermic injections of ether. He had been very successful in the treatment of cholera by this method.

Dr. Henrot reported a number of cases in which a diagnosis of

CANCER OF THE STOMACH

had been made from the fact that a tumor was present in addition to the other physical signs of this affection. The tumor, however, subsequently disappeared, and the patients were apparently restored to health.

Dr. Cunéo had seen cases of simple

ULCER OF THE STOMACH,

in which a tumor had been caused by the cicatrization of the ulcer.

Dr. Thiriar spoke of the

DIFFERENTIAL DIAGNOSIS OF BENIGN AND MALIGNANT TUMORS OF THE STOMACH,

from the quantity of urea in the urine. When the daily excretion of urea was less than one hundred and eighty grains the tumor was probably malignant.

Dr. Duplouy related a case seeming to point to the

CONTAGIOUSNESS OF CANCER.

He had a patient with cancer of the womb, and a few months after she had come under treatment, the speaker operated on her husband for cancer of the penis.

Dr. D'Ardennes spoke of the good effects he had obtained in

PAINFUL AFFECTIONS OF THE STOMACH,

from the use of extract of coca, in doses of one hundred and fifty grains per diem. The best results were obtained in cases of simple gastralgia not associated with lesions of the mucous membrane.

Dr. Bezy gave the history of

AN EPIDEMIC OF TYPHOID FEVER

occurring in a small town near Toulouse, in which the source of the contagion had been traced to a ditch used as a sewer. The specific typhoid microbe had been found in the water of this ditch.

NEW YORK NEUROLOGICAL SOCIETY.

Meeting held Tuesday Evening, Oct. 4, 1887.

Dr. C. L. Dana, in the Chair.

ARTHROPATHY OF TABES.

Dr. Wm. H. Porter presented a specimen of the cord and knee-joint from a case of tabes. The patient was a female, 32 years old. The family history was good. There was no alcoholism and no history of rheumatism in the case. In May of the present year, ovariotomy had been done, and, with the exception of a ventral hernia, the patient had made a good recovery. The cord affection dated from five months previously, and in February last a general increase in the size of the knee had been noted. As early as Dec. 15th, however, the patient suffered pain, and partial luxation had made standing difficult. Examination showed the right knee painful but not swollen. The left presented subluxation, some fluid and enlargement of the lower portion of the femur. There was some dyspnœa and some headache. The patient also suffered with external hemorrhoids, but the urine was negative and the co-ordination good. The right knee measured 18 inches, and the left 21 1–2. The patient was a large woman weighing 300 pounds. The enlargement and the riding of the patella upon the joint were all of the positive symptoms in the case, and it was transferred to the surgical ward. There continued to be a great deal of boring pain in the knee, but no puffy feeling in the feet, no anæsthesia and no ocular trouble. The joint was excised with an apparently good result, but three weeks later, on August 10th, discoloration of the skin on the buttocks and of the small of the back appeared, and in the course of a day or two the part sloughed. The woman died apparently of sepsis from the slough. At post-mortem examination the viscera were found healthy, with the exception of the liver, which was pockmarked with cicatricial depressions. The right knee joint was found in a good condition. Moderate changes of interstitial thickening were found in the cord, especially in Burdach's columns. The question was whether this should be considered a case of ataxia, the only positive symptom being the boring pain. The supposition of tuberculosis was entertained, but the excised joint had failed to show tubercular tissue or bacilli, and erosion of the bones had been the only discoverable change.

Dr. Dana added that the cord in this case was now being examined, and there was no doubt that the posterior columns, particularly the postero-external columns or columns of Burdach, were affected.

Dr. W. A. Hammond suggested that articular affections with locomotor ataxia were infrequent in this country compared with France. He had never seen a case, although many cases of locomotor ataxia had passed under his notice. According to Charcot they were very common, resembling in this the grand hysteria which also seemed limited to France, and even to the wards of the Saltpetrière hospital.

Dr. Porter stated that during the past year he had made post-mortem examinations in four cases of locomotor ataxia. In two of these there were joint affections, and in two, none.

Dr. Hammond asked whether the joint affections were recognized during life. Dr. Porter replied that they were recognized only in one of the cases. He had never seen the condition before this year.

Dr. Weber referred to a case which had been presented the day before at the German Society. He had seen others but not such as would answer to Charcot's descriptions. Rosenthal, of Vienna, also had described severe joint affections in locomotor ataxia, but not in such great numbers. The speaker could point to a few cases out of 70 or 75, but as a rule the affection was not destructive. It was acute. It would come and go, and complete restitution might occur. He referred to two cases. In one there was diabetes and locomotor ataxia, and in the other there was sclerosis of the cervical region of the cord. In this case it looked as though the cartilage and bone were invaded, as there was crackling and change in form. A case like that referred to as presented the day before, with intracapsular fracture and such extreme mobility, he had never seen before in this country.

Dr. Dana had seen only two cases of tabetic arthropathy. He thought that these cases did not under all conditions mean the same. A patient of his own, a case of tabes of ten years standing, slipped and fell, nearly dislocating a joint already loose, so as to present a typical arthropathy of this disease.

MELANCHOLIA DUE TO THE PROLONGED USE OF MORPHIA

Dr. S. B. Lyon presented the history of a case of melancholia due to the prolonged use of morphia for the relief of cardiac pain. The patient was a female of 50 years, who for three years had suffered from a condition diagnosed angina pectoris which morphia only relieved. From two to seven grains had been taken during the day. She had subsequently suffered with terrors and delusions similar to those of the morphia habit, but more persistent. Relief was obtained after withdrawal of the

drug and removal to an asylum away from the unwise attentions of her friends. The cure was sudden, complete banishment of her terrors and delusions occurring in a single day. A curious double consciousness characterized this case. While dominated by her delusions she preserved her ordinary consciousness, thus appearing to inhabit in thought both a real and an unreal realm.

While insane this patient was free from her cardiac pain. This subsequently appeared, but yielded to electrical applications.

Dr. Putnam Jacobi considered the case very interesting. The conception of the Ego as a simple unit is childish. Undoubtedly there may occur changes in the groupings which go to form the consciousness of which the Ego is made up. In this case there was destruction of the ordinary linkings of consciousness and the replacement of the ordinary normal impressions by the formation of a new sphere. The aberrations produced by morphia and other toxic influences could be similarly explained. The suddenness of the recovery in this case further demonstrated that the forced paths of association had ceased to be travelled and the old ones resumed. A process which might be likened to the switching of an engine from one track to another.

Dr. W. A. Hammond objected to the term double consciousness in connection with the case. On true double consciousness so-called the patient was not at the same moment in both conditions, but at different periods led separate lives, during the one condition knowing nothing of what occurred during the other condition, and *vice versa*.

Dr. Spitzka thought that the reader of the paper had used the term with the meaing of the French. The case was assuredly not one of double consciousness, as the term is used by alienists. In double consciousness there is really a double Ego with alternate consciousness.

Dr. Lyon recognized that the case was not one of double consciousness, as Dr. Hammond and Dr. Spitzka had used the term. The patient had, however, a double consciousness in an ordinary acceptation of the word, with a real and an unreal aspect, the latter dominating.

DISCUSSION UPON THE USE OF ANTIPYRINE AND ANTIFEBRIN IN NERVOUS DISEASES.

Dr. T. S. Robertson opened the discussion. He had used antipyrine first in general practice, in acute rheumatism where it had appeared not only to reduce the fever, but to control the pain. This led him to try it in a case of migraine which had resisted aconitia and chloral. He had subsequently given it in over 100 unselected cases of neuralgic troubles. In 90 per cent. of these, relief was obtained in 15 to 45 minutes. He gave it without a stimulant, and diaphoresis was the only ill effect which he had seen.

In the severe pains of tabes he had given 10 to 20 grains hypodermically, or 20-30 by the mouth with a resulting diminution in frequency. In insomnia the sleep was better than that obtained by chloral. The speaker had never seen heart failure. In hyperæxia he gave 40 grains in a dose, and had himself taken 120 grains during 24 hours without any unpleasant result.

Dr. E. Wonitzfelder had had an experience somewhat similar to Dr. Robertson's, but gave the drug with a stimulant, having found nausea and vomiting common where this was not used. He had given antipyrine in 20 indiscriminate cases of headache, obtaining relief in about 50 per cent. He had directed its use in the epileptic ward on Blackwell's Island about three months ago. It had been thoroughly tried but without any appreciable effect. He had used it for the pains of locomotor ataxia, but while the patient had improved he did not attribute this to the drug.

Dr. W. A. Hammond used antipyrine, and his experience had been entirely negative. He had given both antipyrine and antifebrin, both singly and combined, in neuralgia, the pains of locomotor ataxia, insomnia, vertigo, and in headaches both of the anæmic and hyperæmic variety. His method of administration has been in 15 grain doses three times a day, continued for from two to three weeks. A new drug was not needed to shorten an attack of migraine. A hypodermic injection of morphia would do it, or 100 grains of bromide of sodium, or 1-100 grains of glonoin, according to the variety. In a case of tuberculous meningitis in a child of two years he had given 4 grain doses of antipyrine for the relief of pain, and had signally failed. He had given it in epilepsy without result.

Dr. Dana asked whether Dr. Hammond had given antifebrin in epilepsy. Dr. Hammond had given both antipyrine and antifebrin in 15 grain doses with similar results, sometimes combining the two. He referred to the insolubility of antipyrine, making administration difficult.

Dr. Geo. W. Jacoby thought it serviceable to hear the other side of this question. His own experience had resembled that of Dr. Hammond. Antipyrine gave some relief in migraine, at least following the first or second administration. It sometimes cut short insomnia, but that about limited its usefulness in this field. It was not without danger. He had seen collapse from a dose of 20 grains.

Dr. Putnam Jacobi has given antifebrin in the Infirmary to a child with pleuro-pneumonia, and with lowering of the temperature relief from pain also was obtained, although the physical signs remained unaltered, and defervescence occurred in a typical manner upon the sixth day.

Dr. Sachs believed that antipyrine could be recommended only in migraine. Possibly also in headache of a neurasthenic type. Cases should be followed for a number of months. The results from two or three administrations should not be relied upon. He had given it in a dozen cases of migraine with relief within 20 minutes of its first exhibition, and in no case had it been necessary to repeat the dose more than two or three times at intervals of an hour. The only unsatisfactory cases had been those of the spastic type. The paralytic type had been in every case relieved. In one case, that of a man of 32 years, the condition had resisted all previous treatment. The patient every four weeks had to go to bed from 12 to 36 hours, and was incapacitated for work for several days. Antipyrine does not entirely relieve the headache in this case, but the patient is able to continue his business during the paroxysm. In the speaker's experience about 20 per cent. of the headaches of neurasthenic origin would be relieved. In headaches of anaemic and gastric origin the treatment has been unsatisfactory. In insomnia with and without migraine, antipyrine has appeared to act as a true narcotic. Sleep of 9 1–2 to 10 hours followed the administration of 20 grains. He had used it in the lightning pains of locomotor ataxia and in peripheral neuralgias, particularly trigeminal and, sciatic, without result. Antipyrine was not a panacea, and the speaker thought that it should be used carefully. He had met no bad results himself, but from the reports of others it was evident that such results could occur.

Dr. Dana expressed surprise that Dr. Hammond had been so unsuccessful in the use of antipyrine, and suggested that he keep a closer watch upon his clinical assistants. One of them he knew to have been relieved of a most violent migraine by antipyrine, and this gentleman, he understood, was freely prescribing it in Dr. Hammond's clinic at the post-graduate school. In the treatment of epilepsy, antipyrine could only be used empirically. Antifebrin, on the contrary, has been shown to act as a spinal depressant, and hence could be rationally prescribed. He had seen it produce a marked effect in one case.

Dr. Robertson closed the discussion with the remark that he had found antipyrine soluble in Vichy. He considered a dose of 20 to 30 grains safe. He had not

claimed that it cured, but that it acted as a palliative in the conditions named.

In the absence of Dr. Starr, Dr. Sachs exhibited a papier maché model of the human brain.

The Society then adjourned.

Correspondence.

OUR PARIS LETTER.

(From Our Special Correspondent.)

ALCOHOLISM AND ITS EFFECTS IN PARIS. THE PROGRESS OF CREMATION IN FRANCE.

Paris, October 14, 1887.

Owing to the prevalence of alcoholism in this country, the French Government and scientific bodies have taken up the question, and are prosecuting researches as to the best means of suppressing this national calamity. According to one of the writers on the subject, the term alcoholism is a misnomer, as that pathological condition is ascribable not so much to the ingestion of pure alcohol, but to the ingredients with which the latter is adulterated, or it may be that the alcohol is impure. This is the case with all alcohols employed for the manufacture of spirituous liquors. These alcohols are found to contain furfurol in variable quantities, and particularly in those of grain, such as oats, rye and barley. It is obtained by the action of sulphuric acid on oatmeal or on bran, or by the action of this acid on a mixture of sugar and starch, with binoxide of manganese. In this connection, it may be interesting to give an account of the principal liquors commonly in use in this country, and the ingredients with which they are generally adulterated. "Absinthe," a favorite liquor among the French, is almost always manufactured with alcohols of industry, ill rectified, rendered green by the addition of the sulphate of copper, and saturated with resin, so as to give it the beautiful greenish-white precipitate produced by pouring water on it, and which drinkers so much admire. "Vermouth," another favorite liquor, is adulterated with hydro-chloric or sulphuric acid, in order to give it a pungent taste. "Kirsch" is extracted from the leaves of the cherry-laurel, and contains as much as twenty-two centigrammes of prussic acid per litre, instead of five or six centigrammes. Rum is manufactured always with alcohol distilled from beet-root, to which is added ether and formic acid. The "bouquets" of brandies are manufactured by the action of sulphuric acid on castor oil. The coloring matters employed are extracted from logwood, the elder, sorrel, fuschine and coal. Such is the trash which is daily consumed by the Parisians, and the same author makes the following useful remarks: Ethylic alcohol, that is to say, pure alcohol, renders the greatest service to medicine. Taken in moderate doses, it hastens digestion in promoting the production of hydrochloric acid, which is an essential element of the gastric juice. Alcohol being greedy for oxygen, it draws the latter from the blood globules, and thus slackens combustion, instead of promoting it, as is generally believed. Alcohol, even that which is the most inoffensive, penetrates into the organs which it alters, producing fatty degeneration.

The kidneys, the liver, the stomach, the muscles, the nervous system, nothing escapes its work of disaggregation. It engenders pneumonia, tremulousness of the limbs, weakness or perversion of the power of sensation, hallucinations of the sight and of the hearing, paroxysms of lypematic insanity or monomania, delirium tremens, which is an acute stage of chronic alcoholism, to end in general paralysis and death. It is in the Scandinavian provinces where a great quantity of brandy distilled from potatoes is consumed that alcoholism attains its maximum. In France crimes have augmented in proportion to the use of industrial alcohols. Alcohol produces the effects of anticipated old age, which scarcely lasts beyond ten years. Nearly half of the crimes proceed from alcoholism, 13.41 per cent. being suicides, 14 per cent. mental affections. The offspring of persons addicted to drink are subject to hysteria, epilepsy, tubercular meningitis, phthisis, without taking into account that they inherit from their ascendants an irresistible propensity for strong liquors.

The Crematory of Paris is announced to be opened next month. This building, which is situated in the north of the cemetery of Père La Chaise, has the form of a parallelogram, and is three storeys high, surmounted by two chimneys in white stone. The façade is in black and white marble, over which are three domes, and a large vestibule has also been erected. Dr. Brouardel, in a report which he has drawn up on the working of the Crematory, estimates that the furnaces will be able to consume 4,500 bodies annually, which is said to be about the average number of corpses leaving the hospitals in Paris during the year. The Chamber of Deputies has passed the bill authorising Cremation, which however is only optional, and it only remains for the Senate to sanction it before it can be adopted by the public, but it is doubtful if this mode of disposing of the dead will become popular among the French. *Apropos* of cremation, a scientific writer makes the following remarks: The Parisians do not appear to be in the least hurry to deliver their bodies to the flames to be reduced to ashes, notwithstanding the great facilities which are offered them for so disposing of their dead at a trifling expense, and facetiously adds, that in this century of hurry, where every one is breathless and nervous, it would appear that, after having lived by steam, we must necessarily die at the same rate, and it is now proposed that the bodies should be disposed of by electricity, or by what cremationists term electric cremation. Electric or not, or whether the furnace is fed by wood, coal, or coke, is of little consequence, the system will never be in favor except by a few fanatics, for the law of the Church absolutely opposes incineration. The propagators of the crematorial idea wish to support their thesis on the grounds of public hygiene. With the incineration of bodies they say, there will be no more infectious emanations which are set free in the cemeteries, or their infiltration under the soil to corrupt the water of rivers and springs, to the great detriment of the public health. To this, science has responded that the soil is still the best and the most energetic of disinfectants. In the bosom of the earth the work of decomposition of bodies takes place slowly, and by a particular chemical process. To affirm from this that cremation would still more compromise the public health, there is but one step, and this science has cleared up. Since that time the contest has continued between the partisans and the adversaries of cremation. A new element has been introduced by Dr. Hornstein in a work in which he proves that the pretended advantages of cremation were absolutely delusive. Another writer foresees with regret that if cremation became general the Museums of anthropology and of natural history would become bankrupt.

THE METHOD OF ADMINISTERING PHOSPHORUS IN RACHITIS.

To the Editor of the Medical Record.

Sir: In the editorial column of your issue of October 15th, the solution of phosphorus in bisulphide of carbon, proposed by Hasterlik, is mentioned with his claim that it is very stable and reliable.

Hasterlik's formula is as follows:

Phosphori	.1.
Carbon Bisulphide . .	25.
Aquæ	1000.

Inasmuch as this formula has been printed in nearly every medical journal in the country, and no one, so far as I have seen, has as yet questioned its claims, I wish to state my experience with it. Soon after it was first published I tried the formula but found it very unreliable. Bisulphide of carbon is insoluble in water, and can only

be very imperfectly suspended in it. The mixture with water produces a precipitation of the phosphorus from the bisulphide after a short time; in warm weather it may change in a few days.

The oleum phosphoratum, diluted in olive oil, has seemed to me to be safer and more satisfactory than any other mode of giving phosphorus to children. I have cause to use it exclusively in rachitis.

Yours very truly,

L. EMMETT HOLT, M.D.

15 EAST 54TH ST., NEW YORK,

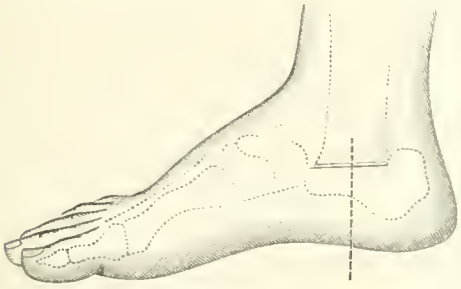
NEW METHOD OF EXCISION OF ANKLE JOINT.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: Will you oblige me by inserting the accompanying cut, as a supplement to my paper on a "New Method of Excision of the Ankle Joint with removal of



the Astragalus." The drawing shows the line of section through the tibia and fibula, and along the upper surface of the os calcis. The drill which spikes the bones together is indicated by the dotted line passing through the sole of the foot beneath the heel, through the calcaneum, and about one inch into the tibia.

JOHN A. WYETH.

AN IMPORTANT OMISSION SUPPLIED.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: A paper by Dr. H. C. Coe, pathologist to the Woman's Hospital, entitled "Some Points in the Diagnosis of Chronic Pyelitis," was published in the last issue of your journal. It had previously been read before the North-Western Medical and Surgical Society, at a stated meeting, June 15, 1887.

After showing, by the authority of Sir Henry Thompson, the difficulties involved in the diagnosis of pyelitis, the author congratulates himself because of the possession of an unusual opportunity for the accurate study of the characteristics of the urine in this disease. He says: "The separation of the pelvic and vesical urine is readily accomplished in the case of a patient now under observation, from the fact that a fine catheter can be passed directly into the pelvis of the kidney through a uretero-vaginal fistula. This is an unusual opportunity to study the different appearances of the excretion in pyelitis-cystitis, and also when the two specimens are mingled." The observations made in this case formed the basis of the author's conclusions.

It should be noted that the case is mentioned simply as being "now under observation." Although it is not so stated, the reader would naturally infer that the case of fistula was under Dr. Coe's observation, and that he passed the catheter into the pelvis of the kidney and obtained the specimens of urine. The name of the surgeon who treated the case should therefore have been stated. As an assistant to the surgeon referred to, and as a former member of the House Staff of the Woman's Hospital, I am familiar with the facts, and am able to supply the omission.

Dr. Nathan Bozeman began in December 26, 1886, to treat a case of pyelitis, by catheterization and irrigation of the pelvis of the kidney. The disease occurred as a complication of a urinary fistula. Dr. Coe, happening to be at the hospital on one occasion, the method was demonstrated to him in my presence. Specimens of urine drawn directly from the pelvis of the kidney were sent to Dr. Coe from time to time for examination. Dr. Bozeman afterwards extended the method of treatment to a case of pyelitis, where no fistulous opening existed. On May 6, 1887, he made an opening in the anterior wall of the vagina, so as to expose the orifice of the right ureter. Specimens from the diseased kidney and from the bladder, as well as the mixed urine, were sent to Dr. Coe in his capacity as pathologist of the hospital, for examination. Both cases were finally cured. In this way an *uuusual opportunity* for the study of the urine of pyelitis, was furnished Dr. Coe. His paper was read while the patients were still under treatment, and their histories unpublished. The omission is now supplied, and any misapprehension that may have existed in the minds of your readers is, I hope, corrected.

Yours respectfully,

WM. B. GILMER, M.D.

9 WEST THIRTY-FIRST STREET, OCT. 17, 1887.

TEREBENE IN THE TREATMENT OF PULMONARY AFFECTIONS.

TO THE EDITOR OF THE MEDICAL RECORD.

DR. CAMMAN'S instructive paper upon terebene—which appeared in THE MEDICAL RECORD of October 8th—increases my conviction that in this drug we have a remedy which needs only to be known to be extensively used and highly prized by those of the profession who have to deal with diseases of the nose, throat or lungs. During the past year I have used terebene in the treatment of thirty patients suffering from various affections of the respiratory tract.

Of the thirty cases, four were fair examples of subacute nasal-pharyngeal catarrh. All rapidly recovered when terebene was used in the form of an inhalation, as well as given internally. Four were cases of subacute laryngitis.

Three were quickly cured, and one greatly improved. In these cases the remedy was used both externally and internally.

Eleven were examples of subacute bronchitis occurring in delicate persons who were frequently troubled with prolonged attacks of bronchial catarrh. Eight of these made good recoveries. One was benefitted but not cured. Two remained unimproved after a fair trial of the remedy.

Four cases suffered from emphysema with chronic bronchitis. All were men past middle life and in poor general condition. Three were very decidely benefitted; dyspnœa much diminished, cough relieved, expectoration lessened, and circulation improved. One was unable to take the medicine. It produced nausea, anorexia and urticaria.

Seven cases of chronic phthisis—selected because dyspnœa and profuse expectoration, were prominent symptoms—received terebene. Six were unquestionably relieved as regards dyspnœa, cough, amount of expectoration, etc. One remained unimproved after a trial of two weeks.

The results of the terebene treatment in my "chest patients" may be summed up as follows: In eleven cases of subacute eight were cured. One improved. Two unimproved. In four cases of emphysema and bronchitis, three received marked benefit. One was unable to take the drug. In seven cases of phthisis, six were decidely relieved. One was not improved.

Thus in about three quarters of these cases, terebene produced decided benefit.

The usual dose was from ten to fifteen drops three or

four times a day. It was given on sugar or in capsules, or in a mixture like the following, which covers the disagreeable taste of the drug sufficiently well.

℞	Terebene	℥ iii
	Oil Cinnamon	♏ ss
	Gum Arabic	ʒ i
	Sugar	ʒ iv
	Comp. Tinct. Cardamon	ʒ iii
	Simple Sirup	ʒ x

Mix. Dose, one teaspoonful, in a little water, three times a day.

In but two cases of the thirty was the stomach disturbed, and in no cases were the bowels affected. About one third of the patients noticed that, during the treatment, they passed a greater amount of water than usual. My notes unfortunately give no information on this point concerning the remaining cases.

Although terebene is evidently not a specific, yet in the light of what has already been reported by various observers, it seems reasonable to conclude that in this drug we have a valuable addition to our list of remedies for the relief of certain trying and persistent pulmonary affections.

Yours respectfully,

CHARLES M. CAULDWELL, M.D.
71 WEST 55TH ST., NEW YORK CITY.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 16 to October 22, 1887.

WOLVERTON, W D., Major and Surgeon. Detailed as member of Army Retiring Board at Washington, D.C., convened by S.O. 78, A.G.O., April 5, 1887, vice Major C. C. Byrne, surgeon, hereby relieved. S. O. 241, A. G. O., October 15, 1887.

GARDNER, EDWIN F., Captain and Assistant Surgeon. Relieved from duty at Fort Reno, Indian Territory, and ordered for duty at Fort Lewis, Colorado. S. O. 241, A. G. O., October 15, 1887.

COCHRAN, JNO. J., Captain and Assistant Surgeon. Now on duty at the Presidio of San Francisco, Cal. Is assigned to temporary duty at Headquarters Division of the Pacific as assistant to the medical director of that division. S. O. 244, A. G. O., October 19, 1887.

EWING, C. B., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, on surgeon's certificate of disability. S. O. 112, Department of Missouri, October 18, 1887.

JARVIS, NATHAN S., appointed to be Assistant Surgeon, U. S. Army, with the rank of First Lieutenant. October 14, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 22, 1887.

BEVER, H. G., Passed Assistant Surgeon. Ordered to hold himself in readiness for orders to the Trenton.

WHITE, S. S., Assistant Surgeon. Ordered to hold hmself in readiness for orders to the Trenton.

STEPHENSON, F. B., Passed Assistant Surgeon. Detached from the Bache and ordered to the Navy Yard, Boston.

STONE, E. P., Assistant Surgeon. Detached from the New Hampshire and ordered to the Bache.

STREET, T.H., Surgeon. Detached from the Patterson and placed on waiting orders.

A Naval Medical Examining Board is now in session at the Naval Hospital, Philadelphia, Penn., for the purpose of examining candidates for admission to the Medical Corps of the Navy. Circulars of information can be obtained on application to the President of the Board.

There are twelve vacancies in the list of assistant surgeons.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 22, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	40	8
Scarlet fever	63	10
Cerebro-spinal meningitis	2	2
Measles	19	4
Diphtheria	103	28
Small-pox	2	1
Yellow fever	0	0
Cholera	0	0

SCLEROSIS OF THE HEART.—According to Huchard the causes of sclerosis of the arteries of the heart may be divided into three groups: the first being due to intoxications, or rather toxæmia, by alcohol, tobacco, malariai and lead; the second group is formed of causes such as the diathetic states of arthritism, gout and syphilis; whilst the last group, and one to which exception may with at least some reason be taken, is composed of causes such as physical, moral, and intellectual over-pressure. The sclerosed heart may be either hypertrophied or dilated, but most often dilatation and hypertrophy are associated. Modifications of the form and size of the heart are the direct consequences of the initial vascular lesion, and not of the ensuing sclerosis. The common lesion is obliterating arteritis of the small coronary vessels, and it takes place slowly, so as to allow of time for compensating hypertrophy and for sclerotic lesions to develop. If the arteritis is of more rapid progress, dilatation of the heart and alterations of the heart-muscle fibres are the preponderant changes. Three histological varieties of cardiac sclerosis may be differentiated, following Weber: (1) perivascular sclerosis due to the propagation of inflammation; (2) the dystrophic sclerosis from regional ischæmia; and (3) mixed sclerosis. The changes in the muscle fibres are but imperfectly known. Two of the principal alterations are simple atrophy and the vitreous degeneration of Zenker. Nosographically, cardiac sclerosis is one of the anatomical expressions of arterio-sclerosis of the heart. Weber regards arterio-sclerosis as the outcome of certain etiological conditions, amongst which must be ranged heredity, certain hygienic habits, and various chronic intoxications.—*The Lancet, September 24, 1887.*

EPHEDRIN is the name of a new mydriatic discovered by Professor Nagai, of Tokio. It is obtained from *Ephedra vulgaris*, rich, variety *helvetica*. It is cheaper than atropin, has no constitutional effects, and does not paralyze accommodation, or only a little.

ETHER INHALATION IN TETANUS NEONATORUM.—A Belgian physician, having a case of trismus neonatorum, and having repeatedly given chloral and ether per rectum without producing any effect, the child rapidly becoming worse and seeming in imminent danger of death by asphyxia, determined to administer ether by inhalation. In addition to this, artificial respiration was employed from time to time by means of a tube inserted into the nostrils. Some pieces of Rigollot's mustard leaves were also applied to the chest. The child was laid on its side, according to a suggestion made by Marion Sims. The result of this treatment was that in a few hoars the little patient's condition had improved to a very marked degree. The next day profuse perspiration occurred and the spasms entirely ceased. Shortly after this the child was convalescent.

A CASE OF GASTROSTOMY FOR CANCER OF THE ŒSOPHAGUS.

BY J. COLLINS WARREN, M.D.,

ASSOCIATE PROFESSOR OF SURGERY, HARVARD UNIVERSITY, SURGEON TO THE MASSACHUSETTS GENERAL HOSPITAL, BOSTON, MASS.

THE operation of gastrostomy for the relief of stricture in this affection owes its origin to the great discomforts attending the treatment by dilatation, the very little benefit to be derived from it, and the aggravation of local complications which attend the spread of the disease from the walls of the œsophagus to the surrounding structures. The surgeon who has the patience and perseverance to carry out the probang treatment is likely to be rewarded for his pains by being regarded as the author of some of the perforations found at the autopsy to extend into the trachea or mediastinum.

Gastrostomy, although adopted at first with considerable enthusiasm, has not had, so far, a very brilliant career, and some surgeons have already begun to raise their voices against it. The chief objection to this operation appears to be the difficulty in so managing the gastric fistula that considerable leakage of the contents of the stomach shall not take place. Most of the reports dwell upon the necessity of making a very minute opening into the stomach, so small that it is necessary to seek for it with a probe when the feeding-tube is to be introduced. Details, as a rule, are not given, so that it is difficult for one who operates for the first time to obtain the desired information.

The present case is therefore reported mainly for the purpose of describing the difficulties encountered in preventing leakage from the fistula, and the measures which were adopted for overcoming them.

J. A. H——, aged fifty-six, first presented himself at the hospital on October 27, 1886. About seven weeks before, he had first noticed difficulty in swallowing food. This symptom had increased so rapidly that at the date mentioned above he could only swallow liquids with considerable difficulty. He had been steadily losing flesh. An ivory-tipped probang, the size of a No. 8 English sound, was passed, with difficulty, into the stomach. The upper border of the stricture was found to be eight and three-quarters inches from the incisor teeth, and the lower border nine and one-quarter inches. Two days later, a probang equal to a No. $9\frac{3}{4}$ English sound was passed. Some relief was obtained by this treatment, and the patient attended as an out-patient, the probang being passed at first three times a week, and later every two weeks. The improvement in swallowing, however, gradually grew less after each sitting, and presently it was found difficult to use the probang, and a No. 23 French bougie was substituted. It finally became impossible to pass any instrument.

The patient at this time was considerably emaciated, but his strength and general condition appeared to be good. He seemed to experience no difficulty in coming from a considerable distance to the hospital. He was, therefore, advised to enter the hospital for gastrostomy. The amount of food taken by him at the date of his entrance, December 27th, was found to be fifty ounces in the twenty-four hours, but this was the result of frequent meals, and persistent efforts on his part to swallow. It probably represented a larger amount than he had been taking for some time before the operation was performed on January 1, 1887. The method selected was that described by Howse in Heath's "Dictionary of Surgery." An incision about two inches in length was made, a finger-breadth below, and parallel to, the cartilage of the eighth rib. On opening the peritoneum the right lobe of the liver presented; this was pushed aside and the stomach was found, greatly contracted and drawn up under the left margin of the wound. It was readily recognized by its peculiar color and appearance, and was drawn down without difficulty. A spot was selected about three inches from the pylorus, and one and a half inch from the greater curvature, to be stitched to the abdominal walls. The peculiarity of the method consists in attaching a considerable portion of the surface of the stomach to the peritoneal surface of the lips of the wound by an outer row of quilted sutures, so that the peritoneal surfaces shall be brought together for the space of half an inch in breadth around the margins of the incision. Seven such sutures were applied, each suture being passed through the outer walls of the stomach by means of fine sewing-needles. The two ends of each suture were then threaded into glover's needles, which were passed through the abdominal walls, and the knot was then tied on the surface of the skin. A needle mounted on a handle is recommended for this purpose, but could not be obtained. Ten superficial sutures united the edges of the incision to the peritoneal surface of the stomach. Here also surgical and intestinal needles were used alternately. This necessitates changing the needles also, which lengthens considerably the time of the operation, which on this occasion lasted over an hour. When finished, however, the result was very satisfactory, as a considerable surface of the stomach was securely attached to the abdominal wall. The single row of deep sutures, as recommended by Sir William MacCormac, ought, however, to effect the same result more speedily. The stomach was not opened; a loose stitch was left in its outer walls as a guide. An antiseptic dressing was applied, and held in place by a broad swathe of plaster.

On the following day the patient was quite comfortable, and was supported by enemata of two ounces of beef-tea, and half an ounce of brandy every two hours. Contrary to the usual experience in these cases he was unable to swallow the smallest quantity of water, and from the time of the operation until his death he was unable to swallow anything. A slight cough, with purulent expectoration, showed itself on this day for the first time, which continued until death.

The wound was dressed on the fourth day, and a slight swelling and redness was noticed between two of the superficial sutures, which were removed, allowing a drop of pus to escape. A pad of cotton saturated with a weak solution of phenyle was substituted for the previous dressing. The stitches were gradually removed, the last being taken away on the ninth day. There was no constitutional disturbance due to the operation, the slight variations of temperature being probably caused by the disease.

The stomach had firmly united by this time to the abdominal walls. On the ninth day, as the patient had several loose operations, the enemata were omitted and the stomach was opened. The operation, which was entirely painless, was performed in the following manner: The spot marked by the guide suture was raised by a pair of forceps, and a fine tenotomy knife was thrust

obliquely into the fold thus raised. A fine gum elastic catheter was introduced, and a small quantity of the contents of the stomach sucked up into it. This consisted of mucus stained with bile in patches. There was no hemorrhage. A small quantity of peptonized milk was introduced immediately. The catheter was allowed to remain in the stomach, and was held in place by a "doughnut" pessary and bandage. A gum elastic catheter was used at first, but the rigidity of the instrument caused some enlargement of the opening, and a soft rubber catheter was consequently substituted. An apparatus was designed after the fashion of this extemporized device, and consisted of a belt and rubber bag perforated to allow the passage of the catheter. When in place it acted somewhat like an umbilical hernia truss.

The cough, which was noticed immediately after the operation, but which had probably existed before, soon became troublesome, as each expulsive effort brought considerable strain to bear upon the fistula. Previous to a cough, in the recumbent position, the abdominal walls were deeply sunken in between the ribs, the cartilages of which were quite prominent; at the moment of coughing they were raised considerably above the level of the ribs, and, if the fistula was allowed to remain open, a quantity of the contents of the stomach would be expelled. The cough was, however, quite loose, and was not spasmodic in character.

The wound healed well, but complete union of the edges of the skin to the edges of the mucous membrane did not take place, a narrow border of granulation tissue separating the two. At the latter part of the month the patient was able to move freely about the ward. By February 1st the opening had become enlarged to about the size of a No. 16 English sound, and considerable difficulty was experienced in keeping it firmly closed; occasionally there was considerable leakage, necessitating a change of underclothing. This was partly due to the great falling in of the abdominal wall, which prevented an accurately adjusted pressure, and partly to the persistent cough.

It became evident now that some valve-like mechanism was necessary to keep the fistula securely closed during the act of coughing. The instrument used in the gastric fistula of dogs is a metal spool composed of separate halves, which can be screwed together so that the two plates can be approximated or separated to correspond with the thickness of the abdominal wall. The stomach being opened at the same time that the incision is made in the abdominal wall, this instrument is put in place, and the edges of the wound are stitched firmly about it. It frequently happens that such incisions fail to heal, owing to the gastric juice which escapes.

Such an instrument cannot, however, be introduced after the fistula is established, as the plates are too broad. With the assistance of Dr. S. J. Mixter, a number of experiments were made with flexible rubber material, which could be folded and allowed to expand after introduction. A flexible rubber button, cut from a piece of rubber ball, was passed over and firmly secured near the end of a piece of tubing. The button being introduced, a small "doughnut" pessary was slipped over the tube projecting from the fistula, and the button was thus held firmly pressed against the inner margin of the fistula.

An apparatus, of which Fig. 1 is a representation, was then made by the Davidson Rubber Co., and was held in place by a pessary as seen in Fig. 2. The tube was made unnecessarily large, but was found convenient for the administration of semi-solid food. It worked well, and leakage was rare after its use. At one time it was found necessary to substitute the shield for a bag which could be inflated after introduction, as the edges of one shield had caused ulceration, but the shield was subsequently used successfully until the patient's death.

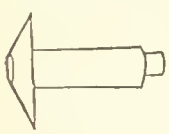

Fig. 1.

The various articles of food administered were as follows: Peptonized milk, beef-tea, brandy, eggs, soup, oatmeal, bread. The daily amount administered varied from eighty to ninety ounces, although occasionally a much smaller quantity was given. Oatmeal-mush and bread-pulp were easily forced in with a hard rubber syringe, also broth containing considerable meat was introduced in this way.

Occasional attacks of diarrhoea showed an imperfect digestion of the food. A malassimilation seemed also to exist, as the patient slowly but steadily emaciated and lost strength, and finally died, May 3, 1887, four months after the operation.

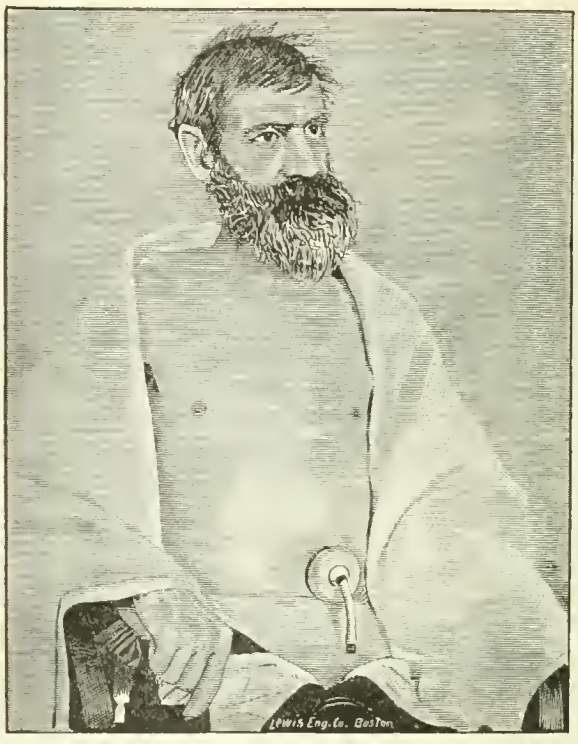

Fig. 2.

The report of the autopsy, by Dr. R. H. Fitz, is as follows: "The œsophageal obstruction was the result of a cancer which had infiltrated the walls for about two inches from the beginning of the œsophagus. The diameter of the tube in the diseased region was contracted to about one-third of an inch. The surface was extensively ulcerated. From the upper portion of the diseased œsophagus a fistulous tract extended into a small circumscribed pleural cavity behind, and to the inner side of the apex of the right lung. Another fistulous communication was established between the lower portion of the œsophageal ulcer and the trachea. The cancer had invaded the bodies of two of the upper dorsal vertebræ. The bronchi contained abundant puriform material, and the left lung showed numerous nodules of tuberculous broncho pneumonia. A part of the anterior wall of the stomach, about two and one half inches from the pylorus, and a part of the left lobe of the liver, were adherent to the superjacent abdominal wall. The stomach was empty, its walls contracted. Pancreas, spleen, liver, kidneys, and bladder were not abnormal, with the exception of marked atrophy of the glandular organs."

No attempt was made in this case to feed through a tube retained in the œsophagus, owing to the narrowness of the stricture.

The experience with a valve-like apparatus for closing the fistula, although not entirely satisfactory in this case, was, nevertheless, sufficiently effective to encourage further trial. It would seem possible to devise an operation which should leave a valvular fold of mucous membrane hanging over the inner opening of the fistula, as existed in the case of Alexis St. Martin. Beaumont thus describes the valve.

"The valve mentioned above is formed by a slightly inverted portion of the inner coat of the stomach, fitted exactly to fit the aperture. Its principal and most external attachment is at the upper and posterior edge of the opening. Its free portion hangs pendulous and fills the aperture when the stomach is full, and plays up and down simultaneously with the respiratory muscles when empty." [1]

The opening in this case was about two and one-half inches in circumference, and was near the cardiac extremity of the stomach. The situation of course greatly facilitated the retention of food.

I have just succeeded in making a fistula in the stomach of a dog, so protected by a valve of mucous membrane that the food and liquid swallowed do not escape, and am at present engaged in further experiments in this direction.

RETINOSCOPY, OR THE SHADOW-TEST.

By J. HERBERT CLAIBORNE, Jr., M.D.,

INSTRUCTOR IN OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC.

In 1864 Sir William Bowman pointed out the fact that "regular astigmatism of the cornea" could be recognized by the mirror of the ophthalmoscope alone.

In 1874 Cuignet, of Lille, first systematized the method of examination, and gave his conclusion in an article entitled "Keratoscopy." The more correct term, retinoscopy, was suggested by Parent, of Paris, in 1880. Forbes, Charnley, Sandact, Hartridge, Juler, Swanzy, Morton, and others have described the method.

As a qualitative and quantitative method of determining the condition of the refraction of the eye it is of undoubted value. Its adoption has been slow upon the European continent, and especially in this country, while in England it is popular and universal.

The following well known and simple experiment will enable us to understand the behavior of the determining elements in retinoscopy, viz., light and shadow: If rays

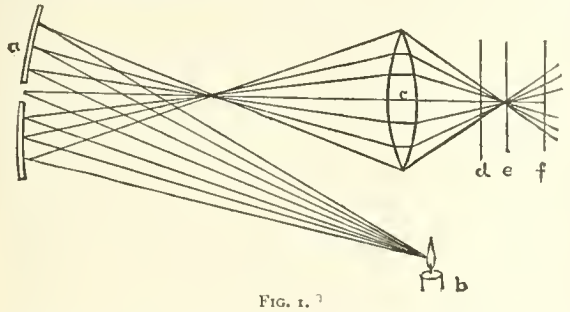

Fig. 1.

of light be reflected from a concave mirror upon a screen placed beyond its focus, they will arrive at the screen divergently. A convex lens may now be interposed in the track of these divergent rays, and a perfectly distinct image of the source of illumination may be formed on the screen. The image will be upright, since the rays have been focussed twice, once in the air at the focal point of the concave mirror as an inverted image, a second time on the screen as the reverse of the inverted, namely, an upright image.

When the lens is held just so as to make the image perfectly distinct, the illumination will be brightest, and there will be around the image a sharply defined, dense shadow, whose edge will more nearly approach a straight line. If now the lens be moved either toward or from the screen, or the screen toward or from the lens, the image will not be distinct, the illumination will appear less bright, the shadow less dense, and its edge more curvilinear, and nice "circles of diffusion" will be formed upon the screen.

If, now, the mirror be turned upon its vertical axis, to the right or left, or upon its horizontal axis, from above downward, or the reverse, etc., it will be seen that the light and shadow move *against* the mirror.

The media of the eye are represented in the above by the lens, the retina by the screen. When the screen is held just so that there is a distinct image formed upon it we have a representation of the emmetropic eye (*e*, Fig. 1); when the screen is brought forward of the focus, we have the representation of a hypermetropic eye (*d*); when carried beyond the focus, a representation of a myopic eye (*f*). We have spoken of the movement of the light and shadow, we should speak more properly simply of that of the light, since shadow is only an absence of light.

As custom and wont have sanctioned *shadow*, we will use it in the following:

The light is placed *over* the patient's head and far enough back to throw the face into the shade. The patient is directed to look over that shoulder of the surgeon which is diagonal to the eye under examintion, *i.e.*, over his right shoulder for the right eye, over his left shoulder for the left eye.

If the patient be under the influence of atropine, we may get the refraction at the macula lutea by making the patient look into our face. If atropine has not been employed, we cannot hope to get the refraction at the macula, but must content ourselves with taking it at the disk.

The surgeon sits or stands at a distance of about forty-eight inches, and uses a concave mirror, generally of nine inches focal distance. (If the A. be of a very high degree the surgeon must be nearer than forty-eight inches in order to see the movement of the shadow distinctly.) The light is thrown into the patient's eye and the mirror is rotated in all directions, vertically, horizontally, obliquely. As the ophthalmoscope is tilted, a shadow is observed to creep from under the iris at the periphery of the pupillary field and pursue a definite course in the latter.

The movement of the shadow, as compared with that of the mirror, furnishes the means of determining the refraction.

If the shadow move *against* the mirror, there may be hypermetropia, emmetropia, or a low degree of myopia.

We have stated in our experiment with the screen and mirror that the direction of the shadow is always against the movement of the mirror, whether the screen be held at *e*, *d*, or *f* (Fig 1).

Now as *e* is situated at the principal focus of the lens, rays coming from this point will pass through the lens and emerge parallel; as *d* is situated within the principal focus, rays from this point will emerge from the lens divergently; as *f* is situated beyond the principal focus, rays coming from this point will emerge from the lens convergently, but this convergence will be so slight that they will unite behind the head of the observer, who is presumably at the distance of forty eight inches.

These rays are practically the same as divergent or parallel rays, since the observer is within their focus.

The movement of the shadow is the same, then, in E., H., and M., which is less than $\frac{1}{48}$.

If, now, the myopia be so great that the far point lies between the surgeon and the patient, the movement of the shadow will be reversed, *i.e.*, it will move with the mirror.

In myopia three images are formed when retinoscopy is used: First, the inverted image of the light formed at the focus of the concave mirror; then the upright image in the eye, and finally the inverted image again in the air. We have spoken thus far of H. and M. in general terms. It is necessary, however, to differentiate simple or spherical aberrations from meridianal aberrations, and in case of astigmatism to differentiate between the various kinds.

We have already shown that in E. the illumination is brightest, the shadow densest, and that the latter's edge most nearly approaches a straight line; that in ametropia the illumination is dim, the shadow less dense, and the

[1] Experiments and Observations on the Gastric Juice and Physiology of Digestion, by William Beaumont, M.D., 1833.

latter's edge is curvilinear in direct proportion to the degree of ametropia.

There is another determining element, the rapidity with which the shadow moves. In emmetropia the far point lies at infinity; in myopia at a finite distance in front of the eye; in hypermetropia at a finite distance behind the eye. The higher the degree of H. or M. the nearer is the far point to the nodal point.

Fig. 2 represents a myopic eye. Let a line be drawn from A, a luminous point on the retina, through the nodal point B, to C. Since the eye is myopic, an in-

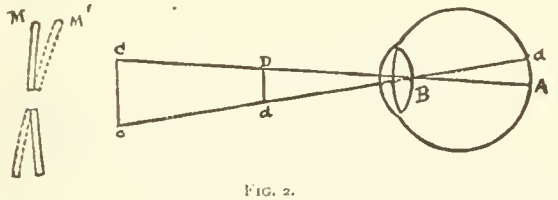

Fig. 2.

verted image of A is formed somewhere on this line, let us say at C. The higher the degree of M. the nearer will the image (far point) be to the nodal point. Let us assume, then, that there is another far point at D. When the mirror is tilted from M to M', C and D move through arcs of circles; D moves to *d* and C to *c*; each moves through its respective arc in the same time. Since C's arc is greater than D's, C must move the faster; conversely, D moves slower than C.

Fig. 3 represents a hypermetropic eye; the far point is situated behind it; we assume the presence of two far points, one at C, the other at D. When the mirror M is moved to M', C moves to *c* and D to *d*; each moves through its respective arc in the same time; since C's arc is greater than D's, C must move the faster. In each case D has been nearer to the nodal point than C.

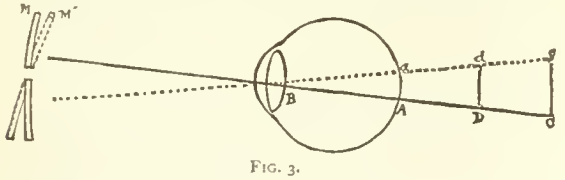

Fig. 3.

The slower the movement of the shadow, then, the greater the degree of ametropia. Since the far point of an emmetropic eye lies at infinity, the shadow moves with the greatest degree of rapidity in E. The characteristic appearance in this latter condition has been described by one writer as an "irregular play of light and shadow." In teaching, we have described the movement of the shadow in E. as a *flitting* movement.

If the shadow move with equal rapidity in all meridians, there is present simple myopia, hypermetropia, or emmetropia. The significance of the direction of the shadow has been given. The differentiation between H., E., and a low degree of M. will be given presently.

In astigmatism the same general rules obtain. If, for instance, the shadow move with the mirror in the vertical meridian, there is M. in this meridian; if it moves in the opposite direction in the horizontal meridian, there may be in this H., E., or a low degree of M. If the shadow move with the mirror in each meridian, but more slowly in one, with greater curvature of its edge and with less illumination than in the other, there is compound myopic astigmatism, and the astigmatism is in that meridian *along* which the shadow moves more slowly, with less illumination and greater curvature of the edge. If the shadow move *against* the mirror in each meridian, but with less illumination, greater curvature of the edge, and more slowly in one than in the other, there is probably compound hypermetropic astigmatism. There is H. in the meridian along which the shadow moves more slowly, but there may be in the other H., E., or a low degree of M., as we have shown. If the shadow move *against* the mirror in one meridian, and *with* it in the opposite, there certainly is M. in one, and probably H. in the other, *i.e.*, mixed astigmatism.

But we must exclude E. and a low degree of M. from that meridian in which we find the movement against the mirror, before we can make a theoretically certain diagnosis. A little experience will readily enable anyone to recognize the characteristic *flit* of emmetropia. As a practical matter, then, when we find a shadow that has not this flit, but rather a well-defined movement against the mirror, we may conclude in favor of H. If the astigmatism be vertical or horizontal, the shadow of the vertical meridian will be seen when the mirror is rotated on its horizontal axis; that of the horizontal meridian when the mirror is rotated on its vertical axis.

If the astigmatism be oblique, the movement of the shadow is entirely independent of the direction in which the mirror is rotated. The shadow will always be oblique, it matters not in what direction the mirror be rotated, since the obliquity of the shadow is due to the shape of the image upon the retina, and not to the direction of the movements of the mirror. We come now to the differentiation between H., E., and a low degree of M., when the movement of the shadow is against that of the mirror. For this purpose the patient should put on a spectacle-frame. If + .5 D ($\frac{1}{80}$), placed in the spectacle-frame before the patient's eye, reverse the movement of the shadow, that is, make it move with the mirror, there is a low degree of M. present.

Suppose the patient is $\frac{1}{80}$ myopic; if the observer stand at the distance of forty-eight inches, the far point of the patient's eye is thirty-two inches behind his head ($80 - 48 = 32$). If + $\frac{1}{80}$ be added to the degree of the patient's myopia, the far point is brought to forty inches from his eye. The surgeon, standing at the distance of forty-eight inches, sees the movement of M.

But suppose that $\frac{1}{80}$ does not reverse the shadow, that it still moves against the mirror; under these conditions we assume that there is no M., or, if present, that it is so insignificant as to need no correction. We next proceed to the exclusion of H. or E. If + .1 D ($\frac{1}{40}$) placed before the patient's eye reverse the shadow, E. is present. It is evident that + .5 D will not reverse it, if E. be present, since this glass will render an emmetropic eye artificially myopic to the extent of $\frac{1}{80}$, and the far point, under such a condition, would lie, as we have seen, behind the surgeon's head. If + $\frac{1}{40}$ be added to an emmetropic eye, its far point would lie at forty inches, since the eye is rendered this much artificially myopic. Under such a condition the surgeon being at the distance of forty-eight inches would observe the movement of M. It is evident, then, that if neither + .5 D nor + .1 D reverse the shadow, H. must be present.

In making an approximately quantitative determination of the refraction of a given case, we may sum up: The less brilliant the illumination, the slower the movement of the shadow; and the more curvilinear (crescentic) its edge, the higher the degree of ametropia.

In astigmatism that meridian is astigmatic *along* which the shadow moves.

For the exact quantitative determination the spectacle-frame, placed on the patient, should be used.

In myopia the *weakest* convave glass which reverses the movement of the shadow is practically the measure. But we have shown that with .5 D of myopia the shadow will move against the mirror; for the sake of greater accuracy, then, — .5 D should be added to the glass that reverses the shadow.

In hypermetropia, practically, the *strongest* convex glass with which the shadow still shows the movement of H. gives the measure. If, however, we add glasses till the movement is reversed, we should subtract 1 D from the first glass that reverses the movement.

The reason of this will be clear if the preceding differentiation be borne in mind.

In correcting astigmatism the axis of the cylinder must

be placed at *right angles* to the meridian along which the shadow moves.

In correcting Ah. and H., or Am. and M., the meridian of less error should be first corrected by an appropriate spherical glass, the other meridian afterward by the appropriate cylindrical glass.

In correcting mixed astigmatism two cylinders may be used, with their axes at right angles to each other, or one meridian may be corrected with a spherical glass; this would obviously increase the aberration in the opposite meridian, which might then be corrected by the proper cylinder, as in the functional examination. If the mirror be plane, the movements of the shadow will be reversed; that is, it will move *with* the mirror in hypermetropia, against it in myopia, while the other signs remain unaltered.

130 Lexington Avenue.

SALINES IN PERITONITIS FOLLOWING ABDOMINAL SECTION.

By J. M. BALDY, M.D.,

PHILADELPHIA, PA.

The subject of abdominal surgery has for the past few years been so freely discussed, and operators all over the world have been so busy collecting together such numerous statistics and perfecting details, that most of the operations performed to-day are fast settling down into their permanent positions in the surgery of the future. The technique of the several operations has been so thoroughly digested that there remains but little to be said in this connection, excepting in a few instances.

The subject of the after-treatment, however, has not been brought so constantly before the profession, and operators are apt to think it not worth while to bring little details, which they deal with every day and take as a matter of course, prominently forward and to notice. It is well known to surgeons that the management of these cases after the operation is of prime importance, and that many a life would here be lost but for the most careful and skilled treatment—and so the results of a seemingly perfect operation be annulled.

The particular phase of the after-treatment which I would urge upon the attention of the profession at this time is the management of those patients in whom peritonitis is beginning to develop, or has already gained full headway. This dread complication, arising when least expected, and sometimes after we have considered the patient out of danger, has in the past been reported as the cause of death in a multitude of instances—in fact, twenty-five per cent. of the deaths following abdominal section are attributed by one writer (Agnew) to this cause. Even with our present perfected methods of operating we still see this disease arising constantly. With this complication ever in mind, I have, since beginning to practise abdominal surgery, followed the example set by Mr. Tait, of never taking any steps to prevent a movement of the bowels after operation, and have fallen into the habit of routinely administering salines in small, often-repeated doses, sometimes as early as the second, generally on the third, day—provided the bowels have not been opened spontaneously at this time.

The results have been, without exception, most satisfactory. The patient has invariably been more comfortable after a passage has been secured, and in cases where a drainage-tube has been used the discharge has been markedly lessened from the time the purge began to act. Where there is much persistent bilious vomiting present most gratifying results are obtained. I have yet to see a single unfavorable result arise from this treatment.

Dr. Wylie, of New York, taking the hint from Mr. Tait, has been in the habit of opening the bowels by enemata and purgatives, "even during the first twenty-four hours after operation;" and he says, "when tympanites or eructive vomiting begins, I at once move the bowels by turpentine or ox-gall enemata, or by a seidlitz powder or Rochelle salts." Dr. J. Taber Johnston, in a paper before the recent International Medical Congress, has urged the same line of treatment in these cases; it has also been the course pursued by Dr. Price, of this city. So it would seem that surgeons are beginning to adopt the saline treatment in preference to the opium in cases where there arise the commencing symptoms of peritonitis. I would, however, go farther than this, and urge that the same line of treatment be followed in cases where the disease is fairly well developed, and that at all hazards the bowels be induced to discharge free watery stools as soon as possible. It is surprising to see how quickly all symptoms begin to subside when this is accomplished. In cases of distention, vomiting, elevated temperature, and quick pulse, etc., Mr. Tait gives small doses of magnes. sulph. every hour until the bowels are opened, and says, "If these symptoms advance to an alarming extent, I use still more active measures to get the bowels moved, *because I always find that as soon as a motion has passed they rapidly disappear.*" My own experience is in exact accordance with that of Mr. Tait, and the following case, which has only recently occurred, well illustrates the rapidity with which all symptoms abate under such management:

Mrs. S——, thirty-three years of age; three children; married ten years; last child five years ago. Has never been pregnant since this event; has always suffered since, and has been gradually getting worse; is only able to work a few days at a time. On September 13th I removed from the left side of pelvis an ovarian cyst as large as a good-sized orange, slightly adherent to pelvic walls and rectum; a cystic-degenerated ovary, and a beginning cyst of the Fallopian tube from the right side; a cyst containing about a drachm of straw-colored serum from the fundus of the uterus, not connected with either tube. As usual, on the third day her bowels were moved gently with salines, and she was doing as well as it is possible for a patient to do; she so continued until she had passed nine and a half days. The stitches had been taken out on the fifth day, and union found to be perfect. I had promised her that she might get up in three more days. I have since discovered that she had been getting out of bed for the past four or five days to shut doors, windows, and to have her bowels emptied. On the 21st of the month she complained of a slight soreness in the left ovarian region. On the 22d, however, she was feeling better, and had not so much pain as the day before. At eight o'clock that night I was summoned to her, and found her just coming out of a violent chill; abdomen slightly swollen; pain increased. She was ordered an ounce of Rochelle salts in divided doses, which she took during the night. In the morning I found she had slept none all night, and was then very much worse—alarmingly so. By noon her temperature and pulse were high, her abdomen extremely swollen and barrel-shaped, tympanitic, and so excessively painful that she could not stand the weight of the bedclothes; knees drawn up; anxious expression of face; dry, parched tongue and lips; vomiting. The small doses of salts had not acted, and she was growing rapidly worse. Influenced by my experience in milder cases, as well as some most excellent results obtained by Dr. Charles Penrose in fully developed peritonitis, I administered an ounce of magnes. sulph. in a concentrated solution, and ordered the dose repeated twice more, at intervals of an hour and a half, should her bowels not be moved in the meanwhile. She was given both doses, besides receiving two or three large (several quarts) turpentine enemata. About two o'clock her bowels were slightly moved, and within the next thirty-six or forty-eight hours she had about fifteen large watery stools. From the time her bowels began to act she began to improve in every symptom—her pulse and temperature dropped; she never vomited after the second passage; by the next morning the swelling of the

abdomen was markedly less; the tympanites had subsided to a very great extent, and her abdomen could be manipulated pretty freely without causing her much pain; her whole appearance was improved, and her countenance showed immense relief. She slept quietly almost the whole of that night, and went on steadily improving until final recovery.

Heretofore I have treated cases of peritonitis on the opium plan. In one case I gradually increased the dose of the tincture of opium until the patient received on one day between sixty and seventy grains of the drug. I have never been satisfied with this kind of treatment, nor have I ever been able to convince myself that it was even logical; it has heretofore been followed simply because all authorities recommend it and strongly condemn purgatives. The rate of mortality in peritonitis is terrible, and the results of the cases treated with opium will stand, I believe, in the future in marked contrast with those treated with salines. Practically, so far as tried, salines have proved themselves satisfactory beyond anticipation, and if such results are continued the time will come when opium will take the place now occupied by purgatives among authorities. Logically, salines are infinitely better than the narcotic. We are taught that opium "puts the bowels in splints," and in this manner keeps the peritoneal surfaces from rubbing together and increasing the inflammation. But the bowels are already in splints, as it were, and anyone trying to make them move will be quickly convinced of this fact—therefore for this purpose opium is superfluous. The drug relieves the pain, it is true, but oftentimes it does not even do this except in enormous doses. Relief of pain is practically all that opium can do for good in peritonitis. It, however, does a world of harm—it helps to keep the bowels in splints, and so favors the formation of those great masses of adherent intestine which we find so often the cause of subsequent intestinal obstruction; also the formation of numerous bands of organized lymph which as often bring a patient to grief in after-years; still worse, it closes all the avenues of escape for the poisonous products of inflammation formed in that great lymph-sac, and in this manner supplies material, the best possible, for keeping up and spreading the inflammation, much more surely than the rubbing together of the parietal and visceral peritoneum will. With salines, on the contrary, the bowels are kept in active peristaltic motion, and this very motion tends to prevent the formation of adhesions and bands; they literally drain the peritoneal cavity of all products of inflammation. This is not merely theoretical, but has been repeatedly observed. A case in the practice of Dr. Penrose showed this most satisfactorily. A large dermoid cyst was ruptured during the tearing away of adhesions, and emptied its contents into the abdominal cavity; in spite of a most careful irrigation a violent peritonitis developed; from the appearance of the first symptom, the drainage-tube which had been put in began to increase its discharges until it was almost impossible to keep it dry and clean; as soon as the bowels were induced to act the discharges diminished and quickly ceased altogether. This patient had about twenty-one free watery discharges per rectum. Theoretically the peristaltic action would cause much pain, but practically the increase is slight, and the pain soon is gone altogether. That the peristaltic action increases the inflammation is, I believe, a myth. The saline so depletes the blood-vessels of the peritoneum and intestines that the inflammation soon has little to feed upon, and the bad tendency of friction has but little weight as against the great good obtained by depletion.

There are dangers, of course, from the administration of large doses of salines and the production of large watery stools, especially to patients who have gone through all the tax on their strength incident to an abdominal section. The patient is much exhausted, and must be fed with strong, concentrated food to supply the place of the nutritive matters lost. One can easily imagine that a case might die from exhaustion, but it will not be necessary to always produce such free purgation as has been done in several instances. Care and judgment must be used in the administration of purgatives, as must be the case with all therapeutics, and a limit put to the number of discharges if they become dangerous in themselves. That a weak, anæmic woman will not bear the drain as well as a better-fed and stronger sister is self-evident. The use of purgatives, it seems to me, is destined to obtain a permanent and valuable place in the after-treatment of abdominal section. As soon as we are able to shake off the inordinate and senseless fear inculcated in our minds by most writers of the day, and the marked results obtained by this treatment are more generally noted, it must come into general use, and we will no longer see purgatives put down as absolutely contra-indicated in peritonitis. To recapitulate, I should suggest that in abdominal sections the bowels be moved, as a matter of routine, on the second or third day after operation; that on the first access of pain and soreness a brisk purge be given at once; in case a general peritonitis is developed, the production of large watery stools as soon as possible, both by purgatives and stimulating enemata, is indicated—these to be controlled in accordance with the strength of the patient in each particular case. Of all purgatives for these various purposes, I believe that the salines, as originally suggested by Mr. Tait, are preferable to any other.

THE MIND CURE.[1]

By MARY J. FINLEY, M.D.

In a little pamphlet entitled "Historical Sketch of Metaphysical Healing," by Mary Baker G. Eddy, President of the Massachusetts Metaphysical College, the author tells us that in the year 1866 she discovered the "science of metaphysical healing," which she "afterward named Christian science." She declares that she was led to this discovery by her "immediate recovery from the effects of an injury caused by an accident, which neither surgery nor materia medica could reach." Other writers on mind-cure declare that Mrs. Eddy obtained, not only her ideas, but her first manuscripts as well, from P. P. Quimby, under whose influence she came in 1862.

Whatever may have been its origin, Christian science, or the mind-cure, is now the most popular craze in some of our large cities; and, like spiritualism, like the skating-rink, and like the airs of "Pinafore," will probably sweep over the country until it has penetrated to the remotest hamlet, and may found a school of medicine as popular as that of Hahnemann. Such being its present status and future possibilities, it cannot be without interest to the medical profession to examine into the theories and practice of its advocates. A system of metaphysics and religion is so closely interwoven with their theory of health and disease—their physiology and pathology—that it is impossible to give the latter without a brief statement of the former. Dr. W. F. Evans, a leader of one of the sects, and probably the most philosophic mind among them, in the preface to his latest work, "The Divine Law of Cure," says that this volume, to which all his other writings may be considered as introductory, is "an attempt to construct a theoretical and practical system of phrenopathy, or mental cure, on the basis of the idealistic philosophy of Berkeley, Fichte, Schelling, and Hegel." Mrs. Eddy disclaims any indebtedness to these philosophers, and declares her metaphysical theory, as well as its application to the cure of disease, to be an original discovery or "revelation." Her philosophy, however, presents nothing new, and in its fundamental features is identical with that of Dr. Evans—which might be called a materialistic idealism, and bears about the same relation to the subtle reasoning of Hegel that a cheap chromo bears to one of Raphael's Madonnas.

[1] Read before the North Central Ohio Medical Society, September 30, 1887.

The efficient cause and active force in nature is God; not a personal deity outside of it, but the force permanently resident in nature. This divine element is the vital germ from which our existence springs. All conscious being is a part of God; "all the millions of the race are but the rising into individuality of the ocean of being, but they never lose their connection with it." "The incarnation is not a solitary miracle, but a universal fact." The body is merely an outward manifestation that the soul forms about itself. "The body neither lives nor dies. It lives from the spirit, and this from the Deity." Material nature exists only as the mind takes cognizance of it, and has no separate reality. There is no reality but spirit; everything outside of us is but a dream of the spirit within us. Literally, "This world is all a fleeting show, for man's illusion given."

Mrs. Eddy says: "All sensation is mind, and mind is God; hence there is but one mind, and this one is infinite, supplying all mind by the reflection, not subdivision, of himself. . . . God is supreme; is mind; is principle, not person; includes all, and is reflected by all that is real and eternal; is spirit, and spirit is infinite; is the only substance; is the only life. Man was and is the idea of God; therefore mind can never be in man. Divine science shows that matter and mortal body are the illusions of human belief, which seem to appear and disappear to mortal sense alone. When this belief changes, as in dreams, the material body changes with it, going wherever we wish and becoming whatsoever belief may decree. . . . The entire mortal body is evolved from mortal mind." After this, it follows quite naturally that "food neither strengthens nor weakens the body—mind alone does this. . . . The truth is, food does not affect the life of man." However, we are not advised to stop eating until we "gain more goodness."

Health, according to Dr. Evans, "is the divine life within us coming to a free activity and expression in all our voluntary powers;" it is a divine gift, an inspiration from God, and in the philosophy of Jesus is viewed as identical with religion.

Disease arises from a lack of proper union with the divine nature, and consists in a false conviction: "A wrong conception and belief ultimate themselves in the body in disease—acute if it be a temporary mental state, and chronic if it be a confirmed mode of thinking." A chronic disease is "a morbid steadfastness of a false idea. . . . When one says that he has a pain in some part of his body, as in his hand, his head, or his stomach, that is a phantom, for the body has no sensation, no feeling." A mind attacked by a belief in rheumatism gives a knee-joint red, hot, swollen, tender, and painful, and runs the general temperature three or four degrees above the normal. "The bodily trouble," says Dr. Marston, "is a reflection or effect of lack of mental ease." There is certainly a concomitant "lack of mental ease," but the general impression has been that it is an effect, and not a cause, of "the bodily trouble." Mrs. Eddy says: "Sickness is a belief, a latent fear made manifest on the body in different forms of inflammation or disease. If you believe in inflamed or weak nerves, you are liable to an attack from that source. You will call it neuralgia, but I will call it illusion." Such being the etiology, pathology, and semeiology of disease, the diagnosis is easy and the prognosis always favorable. "No one ever dies of what is called disease. . . . It is only when faith, hope, and imagination lose their hold upon the organic structure and the soul relaxes its grasp upon the body that it yields" (Evans).

Old age and death—those dreaded spectres of humanity—are indeed phantoms only of mortal mind. Wrinkles, silver locks, second childishness, "sans teeth, sans eyes, sans taste, sans everything," are avoidable evils. Here, in America, is found at last that fountain of perpetual youth so vainly sought by its early explorers. "By keeping the mind young we have a perfect guarantee for continued youthfulness of body. This new system will make us younger at seventy than at seventeen" (Baldwin). Let us believe ourselves young, beautiful, healthy, and immortal, and so we are; "For whatever as to the bodily condition we think to be true, either by a spontaneous impulsion or by a tenacious volitional effort, becomes to us a reality" (Evans).

The treatment of disease has for its primary object the eradication of the false belief in the existence of disease and pain. This is sought in various ways by the leaders of the different sects.

Mrs. Eddy and her disciples discard all material aids: "The principle and rule of metaphysical healing are spiritual. Any material method whereby to demonstrate it is a departure from science. The use of drugs, hygiene, manipulation, alcohol, tobacco, or anything but mind to make or keep man well and happy are so many conspiracies against his health and happiness." They rely entirely upon the effect of her theories on the mind. The perusal of her books is one of the most powerful remedial agencies: "My publications alone heal more sickness than an unconscientious student can begin to reach. . . . Science" (otherwise her theory) "saith to all manner of disease, 'Know that God is all power and presence, and there is nothing beside him,' and they are healed. . . . Science saith to fear, 'You are the cause of all sickness, but you are a self-constituted lie, darkness, nothingness, "without hope and without God in the world;" you do not exist, and have no right to, for "perfect love casteth out fear."' . . . Science reveals the great fact that suffering exists as mortal mind only, for matter has no sensation and cannot suffer. If you rule out every sense of disease and suffering from mortal mind, it cannot be found in the body matter. . . . Demonstrating the unreality of evil destroys it."

Dr. Evans does not entirely discard the use of drugs. He considers all curative agents as "of the nature of a sacrament, a means of grace," and thinks that "the best device for giving faith a material foothold is found in the dilutions and triturations of homœopathy," but "in the human soul reside all the healing virtues and potencies that can be found in medicinal plants and minerals. . . . Their curative properties are something in their spiritual essence which answers to some energy of the soul;" therefore, "by a voluntary and intelligent use of faith and imagination we can effect a cure of disease in ourselves and others." Pain is to be relieved by resolutely putting it out of mind: "A pain, if it is not thought of, is not *felt*. It is thus made a nihility, a nothingness. . . . When we think of it, it passes from nothing to something, for it is only by this that it comes to have any reality to us. Disease without this would be as nothing, for it is only a wrong way of thinking, or, if you prefer it, a false belief. Banish it from thought and it no longer exists." Make the patient believe that he is free from disease and he is cured, for "to be unconscious of a thing is all the same as if it were not. To bring disease into the realm of unconsciousness is to make it unreal; in other words, to cure it." "That of which we do not think has to us no existence. . . . There are many well-attested facts to show that men in the ardor of battle receive wounds of a serious nature without being aware of them until a considerable lapse of time." It naturally follows that the wounds did not exist "until a considerable lapse of time" after they were received.

If the patient is not able to throw off the thought of disease the physician must aid him. This may be done by mental treatment, in which the patient is made to "fix his thought with expectant attention upon the effect to be produced. In addition, the physician thinks the same effect tranquilly and strongly wills it, and believes and imagines that it is being done." At the same time the healer silently goes over a form of "mental argument," in which he may call the disease by name. Various formulæ for these "mental treatments," each claim-

ing to be infallible, are sold for good round sums by the leading healers to young practitioners. The belief of the healer may be communicated by words, but a more spiritual way is by touch, and a still more interior mode of communication is by the eye; the "cogitative gaze" is used by many of the healers, who silently bestow it upon their patients for fifteen minutes at a time. But even this is not essential. When the patient is passive, with his eyes closed, and in sympathy with the healer, the latter can transfer his thought to him at any distance. There is a subtle spiritual principle constantly emanating from us which forms a sort of atmosphere about us; we can concentrate this in the touch, and impress it on any individual, or to any part of his body, or we can direct it through miles of space, even across the Atlantic Ocean.

Dr. Evans recognizes the reconstructive force in nature in language almost orthodox: "This *vis reparatrix*, or reconstructive force in nature, ... is the only remedy that can heal or relieve the injury—heal if it comes within the range of possibility, and if not, alleviate the suffering . . . . *We can assist and greatly accelerate its curative action by thinking in concert with it.* . . . Our thoughts, our faith, our fancy, our remedies, can only be tributary and auxiliary to it."

The first thing that strikes the mind in glancing over this system is that—leaving out of sight the religious and metaphysical side—the theory of disease, its production and relief, here taught, is that which is generally accepted as correct in regard to the manifestations of one disease—hysteria—and it is impossible to avoid the suspicion that the large majority of the cases upon whose cure this system bases its pretensions occurred in hysterical men and women. The second thought is that, in spite of the intimacy of the phraseology employed, there is no essential connection between the theology and philosophy of the system and its principles of medicine. The principle of the influence of the mind on the body, as stated by Dr. Evans in one place, may be accepted by the most regular of the regulars: "There can be no doubt of the influence of a *fixed morbid thinking* in the generation of a diseased action in the bodily organs, nor of the power and importance of a sound mental activity in originating and accelerating a cure."

John Hunter said, "As the state of the mind is capable of producing a disease, another state of it may effect a cure." Indeed, in the language of a popular text-book on physiology, "The influence of the mind in the production, aggravation, and cure of organic diseases is matter of daily observation;" we have all seen striking illustrations of it; it is admitted in every work on practice, and is most forcibly presented in the fascinating work of Tuke ("Influence of the Mind upon the Body"). Yet it is possible that this principle has not yet received proper attention at the hands of the regular profession. Since we have absorbed the something of truth presented by every exclusive system of cure that has heretofore arisen, may we not accept from the mind-curers a wider application of this truth? Upon this, and not upon their theory of existence, depends their success. Upon this has depended the success of every system of medical humbug that has come and gone in the past, or that still flourishes. The vast number of cures of disease which have occurred in all historic times by means purely psychic prove the power of this influence in conjunction with the *vis medicatrix naturæ*.

The medical systems of all barbaric nations depend for their efficacy largely on mental impressions. Voodooism owes its terrors and their relief to the same powerful cause. Chinese and Japanese medicines apparently owe their effects to the thought of the concentrated horrors of their ingredients. The tragedies of New England, during the witchcraft craze, are vivid pictures of sufferings caused and relieved by mental states. The belief in witchcraft lingers still in a mild form in the mountain-valleys of Pennsylvania, and in my childhood I knew of an old woman who could promptly relieve burns by "blowing the fire out," and cure erysipelas by "saying words over it." In England, for centuries, scrofula was healed by the royal touch. When Mesmerism occupied in the popular fancy the place now held by "Christian science," numerous cures were attributed to it. Spiritualism, which promised to revolutionize society, professed also to heal all diseases. We have had water-cures, and steam doctors, and magnetic healers, and Indian doctors, and manipulators, and homœopaths, and each and all have had at some time a "boom."

Modern miracles of healing must be classed among cases of bodily disease relieved through mental impression. Allowing that many of the cures claimed have been only temporary alleviations, that many cases diagnosed as serious or fatal diseases have been slight functional derangements, or forms assumed by those skilful conjurers—hysteria or hypochondria—the fact remains that many suffering invalids have been permanently relieved and restored to health after medical skill had failed to benefit them.

At the time when sacred relics played so large a part in the history of the religious world, their touch was a recognized agency in the cure of disease. The Prince in Longfellow's "Golden Legend," who "was healed in his despair by a touch of St. Matthew's sacred bones," was only one of thousands.

Many priests have been famous as miraculous healers. The cures wrought by several in the present century are numerous and well authenticated. Pilgrimages to noted shrines have been in recent times undertaken for the relief of bodily ailments, much more frequently than for spiritual improvement; this is especially true of the shrines of Mariazell in Austria, Lourdes in France, and Knock in Ireland. These shrines count their yearly visitors by tens of thousands, many thousands of whom return to their homes rejoicing in the relief which they sought.

The "faith-cure" is of comparatively recent date, but large numbers of intelligent people have been relieved of all sorts of ailments by "laying on of hands, anointing with oil, the prayer of faith." Institutions have been founded for the treatment of disease by these means. "There are over thirty 'faith homes' in America to-day. In England and on the continent of Europe can be found a large number, some of them commodious institutions, with a history of many decades of years."

The Mormon elders claim the power to heal the sick by prayer and the laying on of hands, and their success has been in proportion to the confidence in their assertions.

The one thing in common in all these cases is the powerful impression made on the mind, arousing confident hope and directing an intense expectant attention to the diseased part. The claim to some power, occult, mysterious, supernatural, whereby disease shall be overthrown is used to produce the impression. The mind-curers alone proclaim the fact that the relief obtained is through the power of the mind over the body. And this truth thus implanted in the public mind will bear good fruit when the eager acceptance of their fantastic idealism shall have become a curious bit of social history.

The immense number of cases of disease relieved by the influence of the mind, and the strong probability that the same influence is a powerful factor in the causation of the great epidemics that have devastated communities, as well as its undeniable agency in developing the varied forms of hysteria and hypochondria, render it a subject worthy of the careful study of the profession. The investigations now being made of the phenomena of hypnotism may eventually throw a flood of light upon this subject. It would seem that, in these cases, the imagination plays some such rôle in the normal condition as suggestion performs in the hypnotic state.

How the mind acts upon the cells of the gray matter of the cerebrum, and how the nerve-force affects the physico-chemical action in the general tissue-cells which

determines growth, waste, and heat-production, are two points that must be further elucidated before the real physiological action of the real mind cure can be written.

However wide may be the chasm between an intellectual state and the metabolism of the cells composing a bunion, there is a material bridge connecting them. Consciousness has a physical basis in the gray matter of the brain; from this physical side thought is a force liberated in the metabolic changes of the nerve-cells. In the action and reaction of the mind and its material organ the peculiar force of the nerve-cell is set free and projected from cell to cell, from centre to centre, and from centres to periphery. While the ordinary action of the mind in and through nervous matter has no appreciable effect upon the general system, any extraordinary action may send its rebound to the remotest nerve-fibrils, and since every tissue and organ of the body lives and functionates in obedience to the nerves supplying it, every part feels the mental shock; fear breaks in upon the system of the beating heart, pales and roughens the skin, dilates the pupil, and sets the calm muscles in a quiver.

Of the ordinary action of the internal organs of vegetative life the mind does not take cognizance, but a disordered action quickly sends a warning note to consciousness; conversely, morbid mental states interfere with the orderly action of the vegetative organs.

Depressing emotions, long continued, lower the tone of the nervous system and the general nutrition of the body. Peculiar mental conditions may so powerfully affect the nervous apparatus controlling nutrition as to bring about structural changes in a very short time. In the relief of diseased conditions through mental impressions, the concentration of nerve-force, and its projection along a certain line of nerve-fibres caused by the intense expectant attention directed to the suffering part, determines in the affected region a new and vigorous activity which quickly restores it to the normal condition. When the trouble is central in origin and functional in character, the morbid change being in the forces evolved rather than in the tissues evolving them, the remedial action is probably direct. When the trouble is local, involving structural changes, the effect may be produced through those trophic fibres the existence of which, though not clearly demonstrated, is well established; or through the vaso-motor system. The latter, by dilating or contracting the capillary vessels, regulates the force and rapidity of the blood-current through a part, the amount of plasma transuded, and the extent of absorption, and thus powerfully influences the rapidity of tissue-reproduction, or of its disintegration, and the absorption of the products of its waste.

While our knowledge of physiological processes is too limited to enable us satisfactorily to explain the mode in which the thought acts to produce or remove morbid physical conditions, enough is known to show the manner in which it possibly may act, and the fact of such action is well established.

When this fact shall be recognized by the general public, some other proof than the ability to cure real or imaginary ills will be required before a new theory or doctrine can find acceptance, and the popularity of medical, psychic, and religious humbugs will decline.

Effect of Quinine on Uterine Hemorrhage.—A Brazilian journal publishes a paper by Dr. Ramos on the "Effect of Quinine on Uterine Hemorrhage." He cites two cases of patients who suffered, it is true, from malaria, in whom a very few full doses—fifteen grains—of quinine served to check, and indeed to cure, violent and intractable uterine hemorrhage. In one case iron and ergotin had been given internally, and cold injections administered, without much effect, but a single dose of quinine produced a considerable diminution in the amount of blood lost, and a second similar dose completely arrested the discharge, which did not return.

AN UNDESCRIBED ARTERIAL MURMUR.[1]

By H. H. SEELYE, A.M., M.D.,

INSTRUCTOR IN PHYSICAL EDUCATION IN AMHERST COLLEGE.

One of my duties in taking the physical statistics of college students is to examine the heart and lungs of each man. So in the last three classes about three hundred young men have undergone this examination. My plan has been to first examine these organs soon after the man has removed all his clothes, when his circulation and respiration are comparatively quiet and easy, and then a second time immediately after some violent exercise, such as raising the body by the hands and arms as many times as possible, or dipping up and down between two parallel bars until completely exhausted. After such exercise the breathing is deep and rapid, and the heart's action bounding and frequent. More than two years ago, soon after I had begun these examinations, I was surprised at finding certain loud murmurs or bruits about and in the neighborhood of the heart more marked, or only appearing, after such violent exercise, which would have easily led me to diagnose a valvular disease of the heart, had I not soon discovered that it was a phenomenon so frequently occurring in a majority of the men as to make such a conclusion improbable. Though I had previously examined hundreds of hearts in health and disease, yet I had never before come across murmurs with precisely the characteristics of these, nor had I ever seen described anything exactly similar. I at once began to study these sounds carefully, and to look up any literature referring to them, but have never yet seen them described.

In a typical case the first examination, during repose, would probably show nothing unusual. The man would then raise his body by pulling it up with his hands as many times as possible—perhaps ten or fifteen. He would then immediately sit down, and I would apply the stethoscope, pressing on the chest very lightly. Now I would find, under the outer half of the left clavicle, and from an inch to an inch and a half below it, a loud, rough, and blowing murmur, as a rule localized to within an inch or two of this place. This sound would be nearly synchronous with the systole of the heart, or possibly an almost imperceptible interval after the closure of the aortic valve. Over the heart the first and second sounds would be clear and normal. Over the corresponding region, under the right clavicle, the same bruit would be heard, but usually more feebly, and sometimes not at all. A similar souffle would generally be found over each carotid artery, also at a bevel with the lower part of the thyroid cartilage. Though the above description will apply to a majority of the sounds caused in this way, yet it is on account of the exceptional variations, which approach the characteristics of morbid heart-murmurs, that it is of importance to know of the existence of this phenomenon. In some cases it is absolutely impossible to tell whether the sound is valvular or not. Often the bruit will be so diffused that it is perfectly audible over nearly the whole of one side of the chest, posteriorly as well as anteriorly, being but slightly more marked under the clavicle than over the base of the heart. Sometimes, though not so diffused, it is as loud over the heart as under the clavicle. It is generally much more marked, as I said, on the left side, but in exceptional cases the bruit under the right clavicle and over the upper part of the right side of the chest is much the louder.

In many cases where the sounds under the clavicle are quite loud, there will be none in the carotid region; or perhaps only on one side, and that may be on the same or opposite side from which it is heard in the chest. The subclavicular sounds are often greatly increased in loudness when the chest is expanded at the end of a deep inspiration, and they may immediately cease entirely during the act of expiration. An apparently true aortic valvular sound sometimes coexists with this one,

[1] A paper read before the Hampshire County Medical Society, October 12, 1887.

but in the majority of such cases this valvular sound is probably not due to any lesion of the cardiac valves. One of the most suggestive peculiarities in the individuals in whom these bruits are most audible is in the fact that they are usually associated with a thin, flat, and narrow chest, or one in which there is little mobility of the ribs. A consumptive-looking chest is almost certain to present this phenomenon, yet full, large-chested men sometimes give it very markedly. In both these cases, however, the act of percussion and auscultation is apt to show a slight condensation or inelastic condition of the upper part of the corresponding lung. In some unusually inelastic chests these murmurs are very loud, even during perfect repose, and here the liability to confound them with morbid heart-murmurs is very great. Changing the position of the body does not alter the character of these sounds, as they are equally audible in the standing, sitting, stooping, or reclining posture. Where they are absent during complete repose they may sometimes be made apparent after four or five deep and rapid respirations, which will induce an increased activity of the heart's action.

The explanation of this phenomenon possibly involves several factors. I think it depends chiefly upon greater or less compression on certain portions of these larger arteries, which causes a variation at these points in the size of the blood-current. In the case of the subclavian murmur the bruit is probably due to the fact that the increased amount of blood forced out from the vigorously acting heart at each systole so dilates the subclavian artery that it presses against the clavicle or first rib at the point where it is nearest to these bones, and thus the artery is indented at these points and a souffle is caused, according to the well-known law that any obstruction or sharp irregularity in the size of a tube of otherwise equal calibre, through which a current of fluid is passing, will give rise to a bruit at that point. Not only is the artery dilated by the increased blood-current so as to bring it in closer contact with one of these bones, but this approach to the bone is aided by the fact that the increased respiratory effort enlarges the area of the lung temporarily, and this tends to push the artery upward and forward against these bones. For this reason, probably, the sound is loudest at the end of a full inspiration, and as long as the lung remains full, but is apt to cease or greatly lessen during expiration. It is probably of more frequent occurrence in those with inelastic chest-walls, and with more or less condensation or lack of expansive power in the upper part of the lungs, because these facts would keep the bones from moving away from the artery during inspiration, while it would not prevent the expansion of the main portion of the lung from forcing upward the condensed portion, so as to make it press against the artery; and, moreover, such lung-tissue is in itself more favorable to the conduction of sound than that containing more air.

Another element that possibly contributes to these murmurs is the peculiarity of the giving off of the carotid arteries from the larger ones near the point of origin of these sounds. As the left carotid, for instance, leaves the subclavian at so nearly a right angle, it is possible that when the force of the blood-current is greatly increased the disturbance caused by this sudden change in direction of a part of the flow may give rise to such sounds.

The main element in the production of the murmurs heard in the carotid region of the neck is also probably a greater pressure brought to bear on one portion of that artery than in other places, when it is distended overmuch by an increased blood-current. In all parts of its course, except that in the neighborhood of the thyroid gland, the common carotid artery is surrounded or embedded in soft muscular or connective tissue, but at this point it is crossed by the unyielding tendinous portion which unites the two bellies of the omo-hyoid muscle as it passes from the scapula to the hyoid bone. Now, when the artery is suddenly dilated by the rush of blood from each strong systole of the heart, this tendinous portion of the omo-hyoid, with its inelastic fascia holding it down firmly to the clavicle, does not give way to the pressure of the artery as freely as the softer tissues around it, and consequently the vessel is pressed upon harder, and is somewhat indented at this point; thus imposing a slight obstruction to the flow of blood, which is all that is necessary to cause a bruit. A further slight element in the production of this sound, both here and in the subclavians, may be the molecular friction-sound caused by the rubbing of the minute fibres of contracting muscles in the arterial walls against one another, or what is generally called the "muscular sound." The fact, too, that the vessels approach nearer the external surface at the points where the bruits are loudest, helps to account for their localization here.

The reason why these murmurs may in some individuals be heard more loudly in one artery than in another, or on one side than on the other, may depend largely on the variations in the force of the blood-current in different persons, by reason of slight peculiarities in the giving off of the main arterial branches of the aorta. Thus the bruit in the left subclavian is usually the louder, because the current of blood comes more directly from the aorta than in the right, which is a branch of the innominate artery. And as variations in the manner of origin of these large arteries are very common, it is rational to suppose that these may correspond to similar variations from the rule that the loudest bruits are on the left side. Thus, where the bruits are markedly louder on the sight side, the usual curve of the aorta and the points of origin of its branches may be completely reversed, as is sometimes found to be the case.

Why these murmurs are so well marked in nearly half of the men examined, and feebly heard in many others, while they are totally absent in more than twenty-five per cent., is a little difficult to explain. But I account for it chiefly by the fact that in these latter cases the elasticity and mobility of the whole chest is usually greater, the lungs expand more freely throughout, and consequently the whole intra-thoracic circulation is free and unimpeded, so that the heart does not have to labor so hard, and the vessels do not become so greatly overdistended with blood as to produce undue pressure on the neighboring unyielding parts, such as bones, fibrous tissues, and tendons. This theory seems strengthened by the fact that the proportion of men presenting these murmurs is less in the classes that have been longest in college; and in these, by reason of longer use of the gymnasium, the lung-capacity and the expansive power or mobility of the chest-walls always shows an increase over that recorded in the earlier days of college life.

I have endeavored to give the main characteristics of these murmurs, which I call "carotid and subclavian souffles," in order that they may not be confounded with true valvular souffles, as I believe has sometimes been done. The main point to bear in mind is, that the subclavian souffle is almost always the loudest near the outer end, and about an inch below the left or right clavicle, and it may be transmitted more feebly in any direction, while the true aortic obstructive murmur, which it so often closely resembles, is most loudly heard at the junction of the right costal cartilage with the sternum, and from thence is more feebly transmitted along the course of the subclavian and carotid arteries. That such a mistake is possible was illustrated to me by one of the students whom I was examining, and in whom these arterial bruits were very marked after slight exertion. He asked me if his heart was all right, and I answered yes. He thought I must be mistaken, for only a few weeks before his physician at home had examined him, and told him that he had a heart-murmur, which showed a disease of one of the valves of that organ, and he had warned him against over-exertion. On inquiring into the occasion of his applying to the physician for an examina-

tion, I learned that he had felt a little pain in his left side, and in alarm had ridden hastily on his bicycle to the doctor's office to see what was the matter. Of course an examination made immediately after such exercise, when the circulation was unusually active, would reveal a murmur in the subclavian arteries, and in this case it happened that they were quite loud in the region of the base of the heart. I relieved his anxiety by explaining the cause of the murmur, and placed no restriction on his exercising to his heart's content. I have since examined him several times, but find no evidence of any valvular disorder.

I have occasionally found true heart-murmurs in individuals with arterial souffles, but in most cases it was possible to discriminate between the two, and to tell where one ended and the other began.

As I was never warned, in an entensive experience in two first-class medical colleges, and a large hospital where heart-diseases were under daily observation, to look for any such murmurs as I have described, nor have seen them alluded to in any medical books or writings, I have though it a subject worthy of bringing to the attention of the physiologists and diagnosticians of our profession.

Clinical Department.

GANGRENE OF THE FOOT, FOLLOWING FRACTURE—AMPUTATION—RECOVERY.

Dr. J. Edward Green, of Brooklyn, N. Y., reports the following interesting case, illustrating a remarkable recuperative power: "I was called in some time since to see a young negro boy, about nineteen years of age, whose left ankle had been run over and completely crushed by the wheel of a freight-car; the bones of the joint being comminuted to about the size of a split pea. We arrived on the spot expecting, of course, to amputate at once, but owing to the insane objections raised by the boy's father we were compelled to bandage the mangled limb and leave it *in statu quo*. At the expiration of two weeks we were again summoned to the case and found, to our unspeakable astonishment, the boy alive and well, but the injured member in the last stages of putrefaction and literally swarming with maggots. This time we amputated, and, wonderful to relate, at the time of the present writing the boy is in as good condition as before the accident, minus the foot. There was no pyrexia, scarcely any shock, or any of the usual sequelæ attending such injuries."

MORPHIO-MANIA.

Dr. Winslow Anderson, of San Francisco, sends the following communication: "On this far-western slope of civilization, where people are in a constant state of excitement from speculations in mines, stocks, etc., opium smoking and morphine eating are alarmingly prevalent. Women as well as men are the slaves of the habit. A large proportion of the *demi-monde* of San Francisco and the poorer slaves of this drug smoke the 'Chinese pipe.' It is really surprising how many *habitués* visit our Chinese 'dens' and opium 'joints' daily. The writer has witnessed the sickening sight of young white girls from sixteen to twenty years of age lying half-undressed on the floor or couches smoking with their 'lovers.' Men and women, Chinese and white people, mix indiscriminately in Chinatown smoking houses. Another class of people purchase their 'lay outs,' or smoking paraphernalia, and entertain this fiend in their own quarters. Smokers 'hit the pipe' once, twice, and three times daily. Morphine eating and morphine injections are perhaps even more frequently resorted to. Some are equipped with hypodermic syringes and solutions of morphine made by themselves, as the standard Magendie's solution is not strong enough. Injections are used regularly every day, with occasional debauches. Enormous quantities of morphine are consumed in this way and by eating it—ten to twenty grains daily for each individual.[1] The following case is illustrative of my observation relative to the so-called specifics for the opium or morphine habit: The patient, a young lady, for several months suffered with pleuritic effusion of the right side. Morphine powders were prescribed by her physicians, to be used *pro re nata*. The habit grew upon her, and for seven years she had been using one and two one-eighth ounce bottles of the sulphate of morphine a week—ten to twenty grains daily. Everything had been tried to cure her of the habit. Her people being well-to-do, and desirous of saving their child, had used all the 'specifics' the land afforded, but of no avail; she ate the drug just the same. About a year ago she fell into my hands, and my 'specific' which *cured* her was as follows: I succeeded in gaining her confidence and co-operation at the onset; and here let me remark that very little can be accomplished with any specific if enforced restraint or co-operation is not concomitant. I obtained the best hygienic condition for the patient, occupied her mind with some useful employment, supplied and nourished the body to its fullest extent with ferruginous tonics and liberal dietary, as there is usually general ischæmia of the circulation. For cerebral and nervous stimulants, phosphorus, nux vomica, cannabis Indica, etc. The heart was toned up with digitalis and tonics. Sleep was produced by bromides, etc. She was never allowed to refill any of her bottles of medicine, nor was it known to her what she was taking. I gave her morphine daily—a quarter to half a grain less every other day—and in six months my little patient was cured. It is now over six months since she took her last specific for the opium habit, and she has never touched morphine since, nor has she any desire to do so."

[1] It is estimated that there are about ten thousand *white* opium smokers in San Francisco alone. It is next to an impossibility to determine the number of morphine eaters and morphine injectors, as these people belong to our wealthies families and are screened from observation.

TWIN PREGNANCY WITH UNUSUALLY SEVERE SYMPTOMS.

Dr. G. W. Squires, of East Avon, N. Y., reports the following case: "Mrs. G——, aged twenty-seven, pregnant for the first time. In the second month of her pregnancy she began to suffer from vomiting, raising large quantities of a glairy, tenacious mucus. The nausea and vomiting increased in severity, and were accompanied by a short, hacking cough. She was unable to retain any nourishment, and, at the end of four months, when she miscarried, was reduced to a pitiable condition. For two weeks prior to her miscarriage she had coughed, retched, and vomited incessantly night and day. She also complained of chills and fever, which, by the tongue and other symptoms, pointed to a pyæmic or typhoid condition. Hemorrhage and pains coming on, an examination was made. The os was found dilated the size of a five-cent piece, and the membrane was protruding. With the next pain the fœtus was expelled, with the sac intact. The finger was then introduced into the uterus to scoop out its contents when another fœtus, divested of its sac, was found, and also an entire placenta. Upon reaching to the fundus of the uterus a mass was felt, which proved to be hydatids. A second placenta was found implanted over the entrance of the right Fallopian tube, and extending into it a distance of half an inch, and firmly adherent above to the wall of the uterus. The lower half was soft, friable, and badly decomposed, so that it emitted a putrefactive odor when delivered. The uterus was scooped out clean of clots, etc., a dose of ergot was administered, and the patient was watched closely. The uterus contracted down

firmly. There was scarcely any hemorrhage. Almost immediately the patient stopped coughing and vomiting, said she felt better already, and asked for something to eat. The coated tongue cleaned up, the headache disappeared, the fever and chills took their departure, and in five days' time the woman was sitting up. She fully recovered without an untoward symptom. The interesting points of the case were: The coughing and unusually severe vomiting from uterine irritation; the chills and fever from septic absorption; the extension of the placenta into the Fallopian tube; and the immediate relief of all unpleasant symptoms when the uterus was emptied."

Progress of Medical Science.

Acetonuria in Infancy.—The researches of Von Jaksch and of Penzoldt, and many others, have shown that the occurrence of acetonuria is not the special appanage of grave diabetic accidents, but may occur in a great variety of diseases, including fevers, carcinoma, and insanity. There seem also some grounds for believing that even the healthy organism may not be altogether free from the presence of some of this said acetone, which is unquestionably a deleterious body, though it is possible that minute doses of it, like minute doses of many other poisons, are borne by the economy with impunity. Baginsky has given much attention to the occurrence of acetonuria in infant-life, and from his researches it would appear that among children a physiological acetonuria of slight degree and inconstant nature does exist. Pathological acetonuria is common among children suffering from febrile disorders, and the presence of acetone in the urine appears to be related directly to the intensity of the febrile process, since a slow diminution in the amount of acetone in the urine has been observed in pneumonia, from its commencement to its termination. The researches of Baginsky, while admitting the existence in a slight degree of acetonuria during the normal life of infants, prove, so far as they go, that acetonuria is specially to be associated with the febrile state, and, in fact, that it increases with an increase in the fever. It has been proved, also, that a fleshy diet increases acetonuria, while the ingestion of non-nitrogeneous food is not followed by acetonuria. Since acetonuria of a very intense degree may be discovered in the course of convulsive diseases in infancy, it is obvious that many mechanisms are capable of setting up the conditions on which the presence of acetone in the urine depends. It seems clear, however, that neither asphyxia induced by, nor the administration of chloral for, the convulsive seizures is an efficient explanation; nor are there good grounds for believing that acetone can be regarded as a common cause of convulsions, for these spasmodic affections may be unattended with acetonuria, and, further, acetonæmia is not usually the cause of tonic or clonic spasms, as the experiments of Baginsky showed. We neither know for certain the place at which acetone originates, the materials out of which it is constructed, the precise effects on different tissues, nor its ultimate fate in the metabolic system. Conjectures have been made that it originates from hydro-carbons of digestion; but Baginsky has discovered acetonuria in a dog fed wholly on animal food, while acetone disappeared from the urine when the dog was fed exclusively on hydro-carbonaceous material. It appears probable that nitrogeneous material is the source of this chemical body. Baginsky has found a considerable amount of acetone in the urine of a child aged four years, who had swallowed some dilute nitric acid. Grave symptoms, with loss of consciousness, delirium, grinding of the teeth, and small pulse, were observed as the effect of the intoxication; the urine was albuminous also. The acetonuria could not be ascribed to the fever, for the temperature did not go beyond 101° F., but there was considerable disintegration of nitrogeneous material. Although Jaksch admitted that acetone is formed during the lactic-acid fermentation, yet a chemical examination of the contents of the stomach drawn off by washing, and of the intestines as discharged per anum, failed to detect appreciable quantities of acetone; the source of the acetone can therefore hardly be traced to any functional disturbance of the digestive organs.—*The Lancet*, September 3, 1887.

The Eye Diseases of Syphilis.—Many practitioners pay little if any attention to the eyes in syphilitic cases they treat. Others at most look only for specific iritis. That there is a long list of such diseases liable to occur in connection with syphilis is often forgotten. Dr. Jonathan Hutchinson, in his little work on syphilis, gives the following list of these diseases: In acquired syphilis are the following: 1. Acute iritis; usually symmetrical; always in the secondary stage; of fairly common occurrence. 2. Inflammation of the vitreous body; often an accompaniment of iritis in its severe forms. 3. Diffuse keratitis. This is very rare in connection with acquired syphilis. It occurs in the secondary stage chiefly, if not exclusively. 4. Neuro-retinitis. A primary inflammation of the ocular portion of the optic nerve and retina, attended by general haze, but without evidence of choked disk. It is usually seen in the secondary stage. It may affect only one or both eyes. Not common. 5. Scattered choroiditis; gummata of the choroid; choroiditis disseminata. This affection is rare, and is seen only in connection with the late secondary stage. It may be attended by neuro-retinitis, or may occur alone. Usually it is almost wholly confined to one eye. 6. Optic neuritis, with swollen or choked disk; usually seen in the tertiary stage, and in association with meningeal gumma. It is rare, affecting both eyes at once. 7. Serpiginous choroiditis. In this form large patches of absorption are seen, which slowly spread at their edges. 8. Aquo-capsulitis—a form of insidious and chronic iritis, of which the most conspicuous phenomenon is the dotted condition of the posterior lamina of the cornea. With inherited syphilis we have: 1. Acute iritis. It is rare; occurs at about the fourth month as one of the secondary class. It is very dangerous to sight. 2. Interstitial keratitis; tolerably common; usually affects both eyes; often attended with slight iritis and sometimes by choroiditis. Remarkable for its tendency to recover in most cases. 3. Choroido-retinitis; usually chronic and attended by atrophy; most frequent at periphery; may simulate the results of retinitis pigmentosa or approach choroiditis disseminata. 4. Optic neuritis, followed by white atrophy; very rare and almost never recognized, excepting in the atrophic stage. It will be observed that most of these forms of eye diseases are rare in syphilis, but their possible occurrence should always be kept in mind.

The Clinical Significance of Acetone and Diacetic Acid in the Urine.—Dr. Griffith, of Philadelphia, has published a brief *résumé* of this subject (*The Medical and Surgical Reporter*, September 3, 1887), from which we learn the following:

Acetone.—There are several chemical tests for acetone, but as nearly all of them used to be applied to the distillate from the urine, and are, therefore, too troublesome for every-day use, he prefers that of Legal, which is: Dissolve a few crystals of sodium nitro-prusside in a little hot water in a test-tube, add some drops of this to the urine to be examined, and then make the mixture distinctly alkaline with an excess of liquor potassa. A red color is at once produced, but fades after a short time, and has no significance whatever. After it has disappeared add a few drops of acetic acid, whereupon, if acetone be present, a deep violet or brownish-purple color will appear wherever the acid has penetrated. The color often develops slowly, and becomes more intense in the course of a few minutes.

Pathological acetonuria, *i.e.*, where the amount exceeds gr. 1-6 in the total quantity of urine passed in the

twenty-four hours, may be divided into several classes, following somewhat the classification of Von Jaksch :

1. Febrile acetonuria.
2. Diabetic acetonuria.
3. Acetonuria of carcinoma.
4. Acetonuria of inanition.
5. Acetonuria in certain psychoses.
6. Idiopathic acetonuria.

All cases of continued high fever, of whatever nature, are accompanied by the presence of acetone in the urine, and the degree of acetonuria corresponds largely to the elevation of temperature. Diabetic acetonuria is another very common form. It appears to have no relation to the degree of glycosuria. Its development in diabetes is sometimes ushered in by headache, loss of appetite, disordered digestion, a sense of weakness and other unpleasant subjective symptoms ; but these soon disappear, though the acetonuria persists. It seems to be without clinical significance, except that it is more apt to occur in grave cases, and is a frequent precursor of diacetic acid in the urine. Acetonuria is not infrequent in carcinoma of the stomach and bowels, even before cachexia develops. Its onset is accompanied by symptoms similar to those seen in diabetic acetonuria. Cachexia probably develops earlier in those cases in which an abnormal amount of acetone can be detected. Inanition from whatever source is very often accompanied by large amounts of acetone in the urine. This substance has also been detected in the urine in certain instances in psychoses attended by great mental excitement. The sixth class contains those cases in which there is an auto-intoxication by acetone. They are instances of acetonæmia, and though they occur with great rarity, it is well to be on the lookout for them. They are characterized in some cases by restlessness, excitement, and delirium, and then by coma and death ; while no cause can be ascertained, but the urine is found loaded with acetone. In other cases there is extreme languor and other indefinite symptoms. In a few instances reported by Von Jaksch epileptic attacks have appeared, dependent solely on the presence of acetone in the system.

Diacetic acid.—Diacetic acid is chemically not far removed from acetone ; but its clinical significance is far different, and its presence in the urine is a most dangerous complication. It is a compound of acetone with one of the organic acids, probably formic acid. As it is very readily decomposed into acetone and carbonic dioxide, the urine obtained for examination must be as fresh as possible.

The test for diacetic acid is very simple. If a few drops of a solution of the chloride of iron be added to urine containing the acid, a Bordeaux-red color will be at once produced. The urine will also *always* answer readily to the tests for acetone, since in the decomposition produced by the addition of the test-reagents for this latter substance acetone is produced and the diacetic acid is destroyed.

But the matter is not quite so simple as would at first sight appear, since numerous other bodies may at times occur in the urine and produce the same red color. The fact is especially to be noted that the urine of patients to whom thallin, antipyrine, salicylic acid, and carbolic acid have been administered will give this reaction. The following procedure is therefore to be advised : Add a few drops of the iron solution to some quite fresh urine in a test-tube. If a very heavy precipitate of phosphates occur, filter this and test the filtrate again. If the Bordeaux-red color is produced, a portion of the urine is to be boiled and another portion acidulated with sulphuric acid and shaken with ether. If the red color soon disappears on boiling the urine in which the test has already been made ; if it occur not at all or but faintly in the urine prepared by boiling ; if, finally, the red color produced by testing the ether-extract fades within twenty-four hours, while at the same time the reactions for acetone in the native urine are very distinct, we have to do with diacetic acid. Dr. Griffith calls attention to a mistake still frequently made with reference to this substance. For example, in a clinical lecture by a very well-known clinician, reported in one of our medical journals not many months ago, the lecturer referred to the well-known red color produced by acetone when a solution of the chloride of iron is added to the urine containing it. It is true that some years ago it was supposed that acetone gave this reaction, but we now know that it is an entirely different substance.

The same classification of diaceturia may be made as in acetonuria :

1. Febrile diaceturia.
2. Diabetic diaceturia.
3. Diaceturia of carcinoma.
4. Diaceturia of inanition.
5. Diaceturia in certain psychoses.
6. Idiopathic diaceturia.

Diaceturia accompanying continued high fever is rare in adults, and indicates that the disease will probably run a malignant course. In children it is more common, and possesses no unfavorable prognostic value. Diabetic diaceturia is a most unfavorable symptom, and is the precursor of diabetic coma. It is sometimes ushered in by depression and a disposition to sleep ; coma may at once follow, or the symptoms may disappear though the diaceturia remains, and the patient is liable at any time to develop coma and die. Usually there is no relation between the diaceturia and the degree of glycosuria. Diaceturia in carcinoma may also occur and lead to coma. It has also been rarely seen in certain psychoses and in states of inanition. Idiopathic diaceturia, in which there is an auto-intoxication from the drug, is rare in adults, and a highly dangerous condition. It begins with vomiting, restlessness, and dyspnœa, and terminates in coma and death. In children it is oftener seen, and is usually of less import. Constipation and vomiting, with a thickly coated tongue, are present, attended by an enormous quantity of diacetic acid in the urine.

The presence of acetone in the urine need, as a rule, cause no special anxiety. The occurrence of diaceturia, on the other hand, is always a grave symptom except in some cases in children. It is very important to know of its presence, on account of its prognostic indications. In the present state of our knowledge we are unfortunately unable to hinder the development of diacetic acid in the system, or to remove it when formed. Neither diet nor drugs have any effect on it.

Reflexes in Newly Born Children.—A Hungarian physician has published some observations made in Professor Ebstein's clinic in Prague on the reflexes of newly born children (*The Lancet*). Advantage was taken of the lax state of the muscles of the lower extremities, while the child was at the breast, to test the patellar reflex. Altogether 117 infants under sixteen days old were examined. In all these the patellar reflex was present on both sides, but the strength of the jerk varied a good deal. In some cases there was merely a slight, short, sudden extension of the leg. In others the jerk was stronger and followed by a series of oscillations. Frequently a transient clonic contraction of the quadriceps was noticed. In some cases a slight contraction was observed in the quadriceps of the opposite leg. The knee reflex is stronger immediately after birth than during the second week. Premature and badly developed children have a weaker knee reflex than heavier children born at term. The abdominal and eyelid reflexes were also noted. The cremaster reflex was present in all the forty-nine male children except nine, and in these the testicles were high or else hydrocele was present.

Apoplexy of the Severe Type should be treated by compressing the carotid of the affected side, says Mr. Leonard Braddon, and in this way hemorrhage arrested. If the coma continues he suggests trephining to relieve the intracranial pressure.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 5, 1887.

RECENT OBSERVATIONS OF THE MICRO-ORGANISMS IN THE URETHRA AND THE URINE.

DR. S. LUSTGARTEN and Dr. J. Mamaberg, of Vienna, working in the clinic of Professor Kaposi, have investigated the subject of the micro-organisms of the urine in health and in Bright's disease. These results are of interest from two points of view: First, with respect to their denial of the pathognomonic significance of the micro-organism of gonorrhœa; and, second, their observation of a micro-organism which seems to appear in the urine in connection with acute parenchymatous Bright's disease (*Vierteljahresschrift für Dermatologie und Syphilis*, 1887, 4 Heft, 1 Hälfte).

The conclusions reached by the observers referred to are stated as follows:

The mucous membrane of the healthy urethra forms the soil for a large variety of bacteria, whose differentiation the authors have in large part accomplished.

Normal urine contains without exception micro-organisms whose characters can and have been recognized.

The diagnosis of tuberculosis of the genito-urinary passages, based upon the old methods of distinguishing bacilli by their morphological appearance and staining, cannot certainly be made, and the older observations on this point must be considered as of uncertain value.

The morphological appearances of the gonococcus found in the urethral secretions, especially in chronic gonorrhœa, are not pathognomonic. There is a coccus exactly similar to the eye and to stains. This is called the pseudo-coccus. It differs in its mode of growth from the true gonococcus.

In three cases of acute morbus Brightii there was observed in the urine a remarkable abundance of a streptococcus. This organism gradually disappeared on the subsidence of the disease, and returned on its exacerbation.

This observation of a peculiar micro-organism in acute parenchymatous nephritis has received an independent confirmation by Professor Jaksch, who found it in the urine in a case of erysipelas with intercurrent acute Bright's disease.

CHOLERA AND QUARANTINE.

THE outcome of all the discussions and investigations regarding the cases of cholera recently brought to and developed in the port of New York seems to be briefly this: The arrangements for bathing and feeding, and for the disposal of excreta, at Hoffman's Island, were imperfect, and the personal medical supervision was not quite all it should be. As a result, fresh cases appeared and a longer detention of cases than was necessary occurred. The charge that there was not a perfectly thorough examination and disinfection of the effects of immigrants on the infected ships does not seem to be sustained.

On the other hand, the blame for this lack of perfection in arrangements cannot properly be laid, except in small part, to the health officer. Funds were not furnished him to put the quarantine buildings in order, and the claim of a morning paper, that Dr. Smith ought to have done it out of his own pocket, is most absurd. As well might the over-critical editor be asked to supply funds out of his salary to make his paper somewhat more complete.

The agitation of the matter, however, has no doubt done good and will lead to greater care in the future. The attempt to frighten the public into fear of cholera at this time of year, however, is simply part of the newspaper methods of the day. Cholera is always stopped by cold weather, and an epidemic here now would be impossible.

THE CROWNING ACHIEVEMENT OF OPHTHALMIC SURGERY OF THE PRESENT CENTURY.

UNDER this title Dr. L. Webster Fox describes in the *Medical and Surgical Reporter*, Professor von Hippel's operation for the transplantation of the rabbit's cornea to that of man. By this operation Von Hippel has restored sight to an eye practically blind, and Dr. Fox predicts that it has a brilliant future in doing this kind of work. He saw the patient upon whom the first successful operation was performed, and learned its technique. We cannot do better than furnish to our readers Dr. Fox's very clear and complete description.

The patient operated upon was a young, healthy peasant girl, nineteen years of age, who suffered with a leucoma of the cornea of the right eye, obscuring vision to such an extent that qualitative perception of light only remained. The leucoma simplex obscured the central portion of the pupil, leaving, however, a circle of clear cornea at its outer margin, probably two mm. wide. The instrument devised by Prof. von Hippel for performing this operation is most ingenious. The trephine is driven by a clock-work and the cylinder is graduated so as to regulate its cutting depth in the cornea. The leucomatous cornea opposite the pupil was removed by this instrument. The eyelids were separated by an ophthalmostat; then, under the influence of cocaine, the trephine was placed on the cornea perpendicular to its plane, the cylinder so graduated as to cut a certain depth, 0.7 to 0.9. This cylinder is then put in motion by a spring clock motion much after the manner of a Dudgnon's sphygmograph; the hand simply steadies the instrument against the probe; after the circular incision is made comes the most important and delicate part of the operation, *i.e.*, the dissection of the leucomatous tissue from Descemet's membrane. This is done by grasping the inner lip of the incised tissue, and with the greatest care and precision this tissue is removed down to the basement membrane lying in juxtaposition to Descemet's membrane. If, after

the removal of this circular piece of cornea, it is found that Descemet's membrane bulges forward through the circular opening, which in almost every case it does, a paracentesis of the anterior chamber is made at the corneo-scleral margin, relieving the intra-ocular pressure.

The rabbit selected from which to obtain the graft is a young, healthy doe. The eye, which is thoroughly cocainized, is drawn forward by an assistant who has inserted under the superior and inferior recti muscles two strabismus-hooks; the eyelids are kept open with an ophthalmostat; the drawing forward of the globe enables the trephine to be inserted and watched more accurately in its incision; the cut is made through cornea and *Descemet's membrane;* this graft is then inserted in the incision made in the patient; a fine probe running through the cylinder of the trephine is pushed downward, forcing the graft into place; after the removal of the trephine the upper eyelid, which is drawn forward and downward, is pressed against the inlaid tissue, all being held firm by a pressure-bandage, delicately adjusted, the patient, of course, lying on his back. After *three* days the bandage is removed, and the eye examined. If the graft is *in situ*, it will probably be somewhat hazy; if the edges have not turned upward, a successful result may be prognosticated.

Dr. Hippel recently showed a second patient and demonstrated his operation before the Ophthalmological Society of Heidelberg. The patient was found to have a visual acuity of $\frac{20}{200}$, and read Jaeger's No. 6, from which it would be inferred that the new cornea did not clear up completely.

MEMBRANOUS ENTERITIS.]

Dr. James B. Field has written a meritorious contribution to the subject of membranous enteritis, it being the essay which received the Fisk Fund Prize during the present year. The author has collected the records of all previously reported cases, 113 in number, and contributes three hitherto unpublished histories of his own. By analyzing these, some errors which have appeared in current descriptions of the disease have been eliminated, and a very comprehensive, and presumably accurate, account of an interesting affection is furnished. Membranous enteritis has been observed by various persons since the days of Fernel (1554), and has received nearly forty different names by as many European and American writers.

The disease is not infectious, nor is it transmitted by inheritance. Climate, season, and race seem to have little to do with its causation. The patients are usually in middle life, and over eighty per cent. are women. They are also, as a rule, of nervous temperament. Long-continued intestinal irritation from constipation, violent catharsis or warm food, prostatic disease, infectious fevers, and erysipelas have been classed among the causes.

In typical cases, the patient, after having suffered from various digestive and nervous disturbances, begins to have, nearly every month, peculiar attacks lasting about a fortnight. These consist of abdominal pains followed by the discharge from the bowels of membranous shreds or tubes composed of mucus. The bowels are irregular, the tongue coated or raw; nervous symptoms often appear. These periodical attacks continue usually for years. The membranes discharged are of a yellowish or grayish white, of various degrees of consistency, and of the thickness of a piece of paper up to a quarter of an inch. The membranes are in the shape of strips, shreds, or in complete tubes. Rarely, complete tubes or even solid cylinders are passed.

Chemical examination shows that the casts are composed of mucin, and that there is no fibrin or albumin present. Microscopically the membrane is found to be composed of an amorphous hyaline matrix, in which is sometimes a network of fine filaments. Bacteria have rarely been observed.

The attacks are, as a rule, accompanied with decided pain at times, and a great deal of discomfort in all cases. A most interesting feature is the frequency with which disorders of the nervous system, such as hysteria, hypochondriasis, mental depression, chorea, aphasia, and various painful sensations, develop. The cases illustrate the power of continuous intestinal irritation in producing neuroses. The urine is generally normal, and there is, as a rule, no fever.

There is some difference of opinion as to whether the disease is truly inflammatory in character. The clinical history rather points to a nervous origin, there being apparently a profound disturbance of the secretory nerves supplying the mucous membrane of the large intestine, for it is this part of the bowel which is chiefly, if not solely, affected. The marked constitutional disturbances of a nervous character also lead to this view, that "membranous enteritis" is a neurosis. Very few autopsies have been made, and these are of a highly unsatisfactory character. They appear to show some inflammatory or eruptive change in the large intestine. In diagnosis, membranous enteritis was sometimes to be distinguished from tape-worm, and more often from constipation, by the discharge of small flakes of mucus. Hydatids, and enteritis from common poisons, may also at times reinstate the disease under consideration. The progress *quoad vitam* is good. Only six fatal cases are reported, and in most of them the patients died of some intercurrent affection. Acute cases can generally be cured, but cases that have lasted for one or two years are very refractory to treatment. There are numberless drugs, topical remedies, and general hygienic measures recommended, but nothing at all like a specific has been found. Attention to diet, to the regulation of the bowels, and especially to the relief of constipation, is necessary. Arsenic has been much praised, and also the washing out of the colon and subsequent injection of mild astringents.

THE DIAGNOSIS OF THE CHOREAS.

The term chorea was first applied to the dance of St. Guy, or chorea Sancti Viti, an epidemic hysterical affection of the Middle Ages. Sydenham, who did not pique himself upon his erudition, and who probably did not know exactly what the St. Vitus dance, as first observed, was, applied this name to the ordinary form of chorea, such as is seen in children.

Since Sydenham's time the name chorea has been given, not only to the disease which he described, but to a large number of other spasmodic affections, with the result of producing no little confusion.

A year ago Dr. Maurice Lannois wrote a monograph

upon the choreas, and distinguished the different types with much learning and skill. In a recent issue of the *Gazette des Hôpitaux*, M. George Guinon publishes an article on the diagnosis of the choreas, which is practically an abstract of Lannois' work, made, we regret to say, without acknowledgment. Lannois gives a list of eighteen different affections which have been referred to as choreiform by various writers.

It is sufficient, however, for ordinary purposes to recognize three groups, viz., that of chorea-major; ordinary chorea, or chorea of Sydenham; and pseudo-chorea. Chorea-major is a name applied to certain hysterical and hypnotic affections, often of an epidemic character. Tarantism, the jumping-disease, and various rhythmical hysterical spasms come under this head. The ordinary type of chorea shows itself somewhat differently in children, in pregnant women and in old people, etc., and is distinguished accordingly as chorea of Sydenham, paretic chorea, hereditary chorea, chorea of pregnancy, and chorea of old people.

The group of pseudo-choreas includes a number of different affections, some of which are often mistaken for chorea proper. Tic de salaam, or eclampsia natans, tic convulsif, and chorea of the larynx and of the diaphragm are instances of this kind. These disorders are generally chronic, and do not run a definite course. They are the evidence, as a rule, of some degeneration or neurotic taint, and must be looked upon, therefore, as decidedly distinct in their pathology from common chorea. Many of these cases are met with in general practice, among children and adults. They are generally regarded as suffering simply from chronic chorea of Sydenham, or perhaps simply as illustrations of bad nervous or mental habits.

THE ORIGIN OF STOMATITIS FROM THE LOWER ANIMALS.

THE attempt has been made to refer the origin of tuberculosis, scarlet fever, and typhoid fever, in many cases, to the cow. These efforts, which would thus make a useful domestic animal the source of manifold contagions, have not been without some success. Suspicion has been fixed upon milk as a source of disease, and sanitary authorities wisely keep a watch upon it. A French physician, Dr. Th. David, of Paris, has recently revived and defended the theory that aphthous stomatitis is sometimes, at least, derived from the cow or sheep. He considers the disease as it occurs in man identical with the foot-and-mouth disease, or aphthous fever, which sometimes attacks the lower animals and appears in an epidemic form. He bases his view of the identity of the diseases on the striking analogy in the clinical history of the aphthous fever and aphthous stomatitis, on the fact that cases have been reported showing apparently a direct transmission of the disease from cows or sheep to man by contact or through the use of milk. Dr. David also cites a case in which a goat was infected by contact with children who had stomatitis, and another case in which stomatitis developed three or four days after drinking the milk of an animal suffering from foot-and-mouth disease. Twenty cases are collected, apparently illustrating the fact that the disease in man can originate by infection from lower animals.

As we have stated, Dr. David's view of the origin of aphthous stomatitis is not a new one, but it has not heretofore gained much of a foothold, and in standard works on the subject this source of the disease is rarely or never referred to.

SHOULD CHILDREN EAT MEAT?

A WRITER in the *Boston Medical and Surgical Journal* affirms that his experience fully corroborates that of Drs. Cloriston and Keith. At one of the large institutions, the Orphans' Home, in this city, meat has been omitted from the dietary o children under eight years of age during the past twenty-five years. In that time the death-rate and sick-rate have been very small, and the managers consider themselves fully justified in continuing their plan.

Considerable more evidence might be brought against the practice of feeding children with meat. We venture to say, however, that none of it will be strong enough to prove that meat should be entirely excluded. There are plenty of physicians who can testify that children may grow epileptic and neurotic though they have never been large flesh-eaters. The dominant races are the meat-eating races, and though children may do well on vegetables and milk, it does not follow that they would not do better.

Dr. Christopher Hufeland, in his classical work on the "Art of Prolonging Life," insists on the importance of prohibiting meat in the diet of children under two years of age. Meat he considers to be too strong and stimulating a nourishment. The "expansive process of teething, and afterward that of manhood, is hastened too much—a great means of shortening life." A meat-diet has also "a bad influence on the whole character. All carnivorous animals are violent, cruel, and passionate."

After the age of two years Hufeland allows a reasonable mixture of vegetable and animal food.

The views of Hufeland have been much extended by some recent writers. Dr. Cloriston, of Edinburgh, says: "My experience is that children who have the most neurotic temperament and diathesis, and who show the greatest tendencies to instability of brain, are, as a rule, flesh-eaters, having a craving for animal food too often and in too great quantities. I have found, also, a large proportion of the adolescent insane had been flesh-eaters, having a craving for much animal food. My experience, too, is that it is in such boys that the habit of masturbation is most apt to be acquired, and, when acquired, seems to produce such a fascination and a craving that it ruins the bodily and mental powers. I have seen a change of diet to milk, fish, and farinaceous food produce a marked improvement in regard to the nervous irritability of such children. And in regard to such children I most thoroughly agree with Dr. Keith, who, in Edinburgh, for many years has preached an anti-flesh crusade in the bringing up of all children up to eight or ten years of age."

If meat had been given in addition, it may be that what is true, according to Cloriston, of Scottish children, is not true of those living in this country. We are decidedly inclined to the old view of Hufeland, that the addition of a moderate amount of meat to the dietary of children over the age of two years is, as a rule, beneficial.

News of the Week.

Is Gleditschine Genuine or not?—Dr. J. Herbert Claiborne, Jr., of this city, who, it will be remembered, was the gentleman who first experimented with the so-called solution of gleditschine (see The Medical Record, July 30 and October 1, 1887), sends us the following note:

"Dear Sir: In view of the recent statements of several analytical chemists that gleditschine, the new local anæsthetic, is nothing but a mixture of cocaine and atropine, I deem that I owe it to the readers of The Medical Record to say a few words on the subject.

"Mr. Goodman has just returned from Bayou Sara, La., where, he states, he has been making the solution of gleditschine. He informs me that he heard for the first time, on his arrival in Bergen Point, N. J., November 1st, of the analysis of the chemists, who find the solution to contain atropine and cocaine. He expressed himself as being earnestly desirous of setting himself right in the eyes of the medical profession, and, in order to convince them of the genuineness of his discovery, he agrees to do the following:

"I, Dr. Claiborne, am to select two medical men of this city; they are to select as a committee of two a botanist and a chemist; the botanist is to examine the leaves which will be used, and is to pass an expert opinion as to whether they are the leaves of the *Gleditschia triacanthos*, and if not, of what tree they are leaves. The chemist is to bring the chemicals necessary, these being indicated by Dr. Seward or Mr. Goodman, and is to make the solution from the leaves in possession of Dr. Seward and Mr. Goodman, under their direction. The chemist is then to test the anæsthetic and mydriatic effect of this solution on a human being or lower animal selected by himself (the chemist), and is to state to the world, through the columns of the New York Medical Record and the *New York Medical Journal*, whether said solution has anæsthetic and mydriatic effects or not. If cocaine or any mydriatic be employed in the process, to say so; if not, to say not.

"The condition to be imposed is that the chemist, on his word as his bond, is not to divulge the method of procedure of obtaining the substance.

"This solution, if it be desired, may be placed in the hands of experts, who may pass judgment upon its anæsthetic and mydriatic properties.

"Bergen Point, N. J., is to be the site of the procedure, or, if it be demanded, any other place.

"No one can fail to be struck by the fairness of this proposition.

"Dr. George F. Shrady and Dr. Frank P. Foster have agreed to act as a committee in this matter.

"Mr. Goodman informs me that he has had shipped from New Orleans a quantity of the leaves of the tear-blanket tree, by one of the Cromwell line of steamers, and that he expects them shortly.

"To my mind the solution seemed to have effects different from cocaine or atropine.

"Moreover, several facts regarding the tree, which have come under my observation, or to which my attention has been called, seemed to warrant the conclusion that the point had not been proven beyond a reasonable doubt.

"In this connection I would say that, with a strong aqueous solution of the gleditschia leaf, obtained through a friend from a chemist in New Jersey, who was experimenting in this direction, I observed in my own eye and in that of my friend a dilatation of the pupil.

"This lasted in my case for several days. His case was not followed up. No anæsthetic effect was observed in either. Every seeming possibility of error was eliminated. A bottle was used for the solution which had never been used for a mydriatic or any other medicine, as far as was known, a new medicine dropper was used, and my own hands were thoroughly washed before commencing. Neither this gentleman nor myself had touched a bottle containing any mydriatic for twenty-four hours. It is pertinent to remark that the dilatation was slight, and that copious and frequent instillations were made for an hour.

"In a recent communication to me concerning gleditschine, from one of the chemists who have been investigating the matter, it was said that Dr. Rusby had stated to them that the 'natives of Bolivia, whenever they are unable to obtain supplies of coca leaves, chew the leaves of a tree which is closely allied to the gleditschia, and which leaves they call *chinchi-coca*.'

"Those who, it is alleged, have made this discovery have been denounced in the most unmeasured terms by certain chemists. It is, therefore, in the highest degree proper that he plain and unvarnished truth should be known. It is to be hoped that we are approaching the finale of this most interesting and perplexing question."

The Medical Society of the State of New York.—The Business Committee of the State Society for the coming session are Doctors F. A. Castle, of New York (Chairman); A. Walter Suiter, of Herkimer; L. W. Whitbeck, of Rochester, Monroe Co. Members of the Society intending to read papers at the next meeting will please notify any member of the Business Committee, or the President, before December 20th.

At the Opening of the New Buildings of the New York Skin and Cancer Hospital, at the country branch, Fordham Heights, on October 29, 1887, at two o'clock, an address of welcome was made by W. Q. Riddle, Esq., President of the Hospital, followed by one on cottage hospitals by Dr. A. Jacobi, President of the Medical Board. Addresses were also delivered by Rev. H. J. Van Dyke, Jr., D.D., and Judge Henry E. Howland. The country branch hospital is situated at Fordham Heights, New York City, about one mile above High Bridge, between Sedgwick Avenue and the old McComb's Dam Road. The new buildings were duly inspected by a large number of friends, and much satisfaction expressed regarding their construction and utility.

The Yellow Fever continues at Tampa, Fla., but has reached no other part of the State.

Dr. H. D. Hull, of Adrian, Mich., was the name of the author of the excellent article on "Jaundice in Typhoid Fever," instead of Hill, as printed. We regret to say that the error was in consequence of the chirography of the author.

The Congress of American Physicians and Surgeons.—A meeting of the Executive Committee of the Congress of American Physicians and Surgeons, for the purpose of organization, was held on October 5th, in the Hall of the College of Physicians of Philadelphia. The special societies were represented as follows:

American Surgical Association, Dr. Claudius H. Mastin, of Alabama.

American Otological Association, Dr. Cornelius R. Agnew, of New York.

American Ophthalmological Association, Dr. D. B. St. John Roosa, of New York.

American Laryngological Association, Dr. J. Solis-Cohen, of Pennsylvania.

American Neurological Association, Dr. L. Carter Gray, of New York.

American Dermatological Association, Dr. I. E. Atkinson, of Maryland.

American Climatological Association, Dr. A. L. Loomis, of New York.

Association of Genito-Urinary Surgeons, Dr. John P. Bryson, of Missouri.

American Association of Physicians, Dr. William Pepper, of Pennsylvania.

The Committee was organized by the election of Dr. Pepper as Chairman, and Dr. Bryson as Secretary.

It was decided to hold the Congress of 1888 in Washington, D. C., on Tuesday, Wednesday, and Thursday, September 18th, 19th, and 20th, respectively. The sessions of the Congress will be held in the evenings, leaving the mornings and afternoons free for the sessions of the special societies participating.

The following officers of the Congress were elected:

President—Jno. S. Billings, M.D., LL.D., U.S.A., of Washington, D. C.

Vice-Presidents—The Presidents-elect of all the participating societies.

Treasurer—Dr. W. H. Carmalt, of Connecticut.

The arrangement of the programme for the sessions of the Congress was referred to the President, the Secretary, and the Chairman of the Executive Committee.

Death of Dr. William M. Chamberlain.—Dr. Chamberlain, who has been an invalid for several years, died on October 31st, at Summit, N. J. The deceased had enjoyed a large medical practice in this city, and was one of our best known and most esteemed physicians. He was born in Hanover, N. H., in 1826. His father was a professor in Dartmouth College, and Dr. Chamberlain was a graduate of Dartmouth both in medicine and in the arts. He came to New York in 1851 to enter Charity Hospital as interne, and left it in 1853 as its chief of staff. At the opening of the war he offered his services to the Government, and was appointed Brigade Surgeon, serving afterward on the Sanitary Commission, and still later in the United States Pension Bureau. In 1863 he resumed practice in New York City, and, devoting himself to the specialty of diseases of women, he succeeded the late Dr. Peaslee in the Demilt Dispensary. He was for many years identified with Charity Hospital as visiting and consulting physician, and also as President of the Medical Board. Dr. Chamberlain was a gentleman of fine presence, agreeable manners, and scholarly attainments. He made a number of interesting and valuable contributions to medical literature. His last literary work was a paper, read before the Section in Practice of the Academy, on the Climate of Southern California.

Washington Obstetrical and Gynecological Society.—At the last meeting of the Washington Obstetrical and Gynecological Society the following officers were elected for the ensuing year: Samuel C. Busey, M.D., President; D. W. Prentiss, M.D., and W. W. Johnston, M.D., Vice-Presidents; George Byrd Harrison, M.D., Treasurer; Samuel S. Adams, M.D., Recording Secretary; G. Wythe Cook, M.D., Corresponding Secretary.

The American Association for the Cure of Inebriety w l hold its semiannual meeting at the Turkish Bath Hotel, Columbia Heights, Brooklyn, N. Y., November 9th, at 12 M.

New York Physicians' Mutual Aid Association will hold its annual meeting at the New York Academy of Medicine, Thursday, November 10th, at 4 P.M.

Death of Dr. Carnochan.—We have to announce with regret the death, on October 28th, of Dr. John Murray Carnochan, at his residence in this city. Dr. Carnochan suffered a slight sunstroke last summer, since which time he had not been perfectly well, but his death, which was caused by apoplexy, was entirely unexpected. The deceased was born at Savannah, Ga., on July 4, 1817. He received his education in Scotland, of which his father was a native, and was graduated from the University of Edinburgh when seventeen years of age. Coming to New York, he entered the office of Dr. Valentine Mott, and soon took his degree of M.D. He paid a second visit to Europe, and attended the lectures of the leading surgeons at the great hospitals of London, Paris, and Edinburgh. Then he returned and began practice in this city in 1847, and soon acquired reputation for original operations. In 1850 he organized the hospital on Ward's Island for the Commissioners of Emigration, and was its chief consulting surgeon for twenty-five years. Soon after Governor Hoffman's election, in 1870, he appointed Dr. Carnochan as Health Officer of this port, which office he held for two years. Since then he has confined himself to his private practice, and to the preparation of a *résumé* of his own operations and his observations and experiences as a practitioner in surgery. This work is being published in parts, and is only half finished.

Ophthalmia in the Russian Army.—Ophthalmia is one of the banes of the Russian army. At present there are over two thousand six hundred victims in the hospitals of the Odessa district alone. These cases are for the most part treated y nurses, and have no skilled medical attendance.

Dr. William H. Randle has been appointed Port Physician of Philadelphia in place of Dr. Henry Leffman, whose term of office has expired.

The Alabama Surgical Association.—The first meeting of the Alabama Surgical Association was held in the city of Birmingham on October 10th. It is the

purpose of this Association to organize the surgeons of the Southwest in such a manner as to impart a new interest in, and to give impetus to, the development of this important branch of science. It is strictly a scientific body, and its incorporators do not desire to participate in the regulation of medical politics. Many able surgeons from Tennessee and Mississippi aided those from Alabama in making the meeting a success. Dr. Rosser, of Birmingham, as president, delivered an unique address on the surgeons of the present compared o those of the past. Dr. Baldwin, of Montgomery, delivered the annual oration.

A Doctor Forced to Steal to Prevent Starvation.—The papers tell a story which, if true, is a very pitiful illustration of professional destitution and failure. A young physician of Chicago was arrested for stealing medical books from the libraries of other practitioners and selling them. When finally caught and arraigned before the justice, he said that he had no practice, and could earn no money. He was actually starving, and was driven to steal on that account. The physician from whom he had stolen appeared and begged that the young man be allowed to go unpunished. He was discharged, but told to leave the city. The story carries its own moral. But as this is an uncertain world, and the young man has been driven from Chicago, it may be just as well for physicians in other cities to be on their guard.

Our Esteemed Homœopathic friends are bound to make a mess of it when they attempt polemics. The *Medical Counsellor*, for example, after reporting, on page 406, two cases of rheumatism treated with large doses of salicylic acid (!), takes up the subject of comparative mortality under regular and homœopathic treatment. It states triumphantly that the percentage of cures in the Michigan Asylum for Insane Criminals (homœopathic) is three! The percentage of cures at insane asylums runs usually from twelve to forty. In some asylums in Ireland under regular control the percentage of cures is eighty! So much for statistics.

A Set-back for the Bacillus of Scarlet Fever.—The report of the Edinburgh committee appointed to investigate the organisms of scarlatina, though not final, throws doubt on the specific character of any of the alleged scarlatinal bacilli. It especially tends to explode the much-talked-of theory that scarlatina is spread through contagion from cows or their milk. The committee doubt if calves are at all susceptible to scarlatinal poison. The *British Medical Journal* says that, "in conjunction with Professor MacFadyean, the committee injected scarlatinal blood into two calves, and fed a third with desquamated scales. All three experiments gave negative results. It will be remembered that the keystone of Dr. Klein's research is the assumption that cattle can take scarlatina, while both Dr. Klein and Mr. Edington lay some stress on the results of the inoculation of their organisms on calves. Mr. Edington inoculated two calves, one of which died within twenty-four hours, and the other, which was only one day old, recovered after a short illness, in which the prominent symptoms were high temperature, inflamed throat, and redness of the skin, followed by desquamation. If the committee definitely show that cattle of every age are incapable of being affected by the scarlatinal poison, the assumption on which Drs. Power and Klein base their views falls to the ground, while the result of Mr. Edington's experiment tells rather against than in favor of the idea that his bacillus is the cause of human scarlatina. A second point of importance is the statement that the microorganism described by Mr. Edington under the name of streptococcus rubiginosus is morphologically identical with the streptococcus scarlatinæ of Klein. According to Mr. Edington, this organism is not present in the blood in the early stage of the disease, and its inoculation into rabbits, guinea-pigs, and pigs gave negative results. Whether, though morphologically identical with Dr. Klein's organisms, it is really the same, has not yet been determined. In connection with this microbe, the fact stated by Mr. Edington in his letter to the committee is interesting, namely, that his brother drank a cultivation of this organism thirty-six hours old, and made directly from scarlatinal blood taken on the ourth day of the disease, without showing any bad result, although the streptococcus rubiginosus was ound in his blood three days later, and although he had never had scarlet fever. It is also interesting to note that the results of the microscopical examinations and cultivations made from the blood were by no means constant. In ten cases of scarlet fever examined microscopically on or before the third day, bacilli and micrococci together were found in three cases, micrococci alone in four, and no microorganisms in the remaining three. The results obtained by cultivation were very similar; in four out of nine cases bacilli and micrococci appeared in the culture material, in two micrococci alone, and in three the result was negative."

Attempted Suicide of the Physician-in-Chief of the Vienna Hospital.—It is stated that Dr. Länger, *primarärzt* of the Vienna Hospital, after a somewhat unpleasant interview with Professor Boehm, the newly appointed director of he hospital, took a large dose of morphia, with the intention apparently of committing suicide. He was, however, promptly treated by the performance of tracheotomy and the mechanical inflation of he lungs through the opening. By this means his life was saved. Dr. Länger, who is greatly respected, has been for some time past subject to melancholia.

The Two Forms of Chronic Laryngitis.—Referring to the improved condition of the Crown Prince, *The Lancet* says that, roughly speaking, there are two forms of chronic nflammation of the larynx: One in which the inflammatory process is confined to the mucous membrane, and gives rise to intermittent disphonia, or loss of voice. This condition may last a whole lifetime without undergoing any further development. The second kind of inflammation, on the other hand, often causes interstitial changes, resulting in thickening, false excrescences, ulcerations, etc. Although the Crown Prince's affection belongs to the latter category, no unfavorable development has hitherto taken place, and the fact that his general health is very good makes it in the highest degree probable that there should be any such untoward sequela.

A New Medical Quarterly.—*The American Journal of Psychology* is the name of a new quarterly edited by Professor G. Stanley Hall, and published at Baltimore. It is devoted to the physiological rather than metaphysical side of psychology, and its first issue contains articles by physicians as well as physicists and psychologists.

A Monument to Bretonneau, Trousseau, and Velpeau.—*The Lancet* says: "The fame of the three men whose names are given above is world-wide. It is less known that they were each natives of Touraine, and it was to perpetuate this fact, and at the same time to erect a worthy memorial of them, that a movement was initiated in 1885 by the medical faculty of the Department o Indre-et-Loire. The result of their appeal to the medical profession and the public has been satisfactory, and on the 30th inst. the monument, which has been executed by two artists of Paris, MM. Sicard and Lalaux, will be unveiled in the Square de l'Archevêché of that city. The monument consists in an allegorical figure, holding in one hand the symbolic shield with three towers, and with the other crowning her three sons, who are represented in medallions on the top of the pedestal."

Sir William Gull is suffering from a mild form of hemiplegia.

The Inter-marriage of Cousins.—The Legislature of Illinois has passed a law making the inter-marriage of cousins a penal offence. This is an unwise law, first because it interferes unduly with personal rights, and next because it is not called for. The marriage of cousins who are each of healthy family and physique, and especially if they are of different temperaments, is quite free from danger.

Sir James Paget, in a recent address to medical students, relates the following anecdote of Abernethy, and adds his comments: "Let me say," Sir James begins, "that Abernethy ought to be remembered not as a rough wit or a mere eccentric, but as a man of rare sagacity, an admirable surgeon and teacher, and one of the most graceful scientific writers of his time. Entering his lecture-room at the beginning of a session, he looked round at the crowd of students and said solemnly, 'Good God! what will become of you all?' Many years afterward I tried to find an answer to such a question; tried in the dullest way—by statistics. I traced the careers of a thousand of my pupils. I need not give the numerical results; but the general and certain rule was as I have said: such as the student had been, such was the practitioner. There were some few exceptions, but the general rule was clear; and so you may be sure it always will be. So, if you are to be hard-working scientific practitioners, as I hope you will be, you must be hard-working scientific students; you must be always learning for yourselves; always observing, recording, collecting truths; searching for new truths as well as accepting those which you will be told by your teachers. And let me say again and again, this will be the best way by which you may become as good practitioners as you possibly can be, and may go on in practice constantly becoming better and constantly acquiring fresh knowledge for others as well as for yourselves."

A Prince of Quacks.—Under this title the *British Medical Journal* gives an account of a Parisian charlatan, from which we learn that the seats of civilizations may rival the provincial towns of a new world in credulity: "Some weeks ago a quack opened a splendid suite of rooms in a building on the Grand Boulevard. He had footmen in plush and pages in livery, distributed handbills by the million, and announced that he had an infallible method of curing hoarseness and diseases of the throat by inhalation. This prince of quacks did not purchase a degree, like many of his compeers, but had himself heralded on bills and in the newspapers as Dr. Pitchitchine, Beloochistan, Member of all the Academies. The big, foreign-sounding name, which the doctor had culled at random from an atlas, and the style of his rooms, are said to have produced a great impression on the minds of those unsophisticated people who, despite the enlightenment of the age, still abound, even in the great centres of civilization; and among those was an actress, who sought this pseudo-throat-healer for hoarseness from which she was suffering. The patient, we are told, went to Pitchitchine's magnificent establishment on the Boulevard. The folding-doors were thrown open by a gorgeous flunkey, and the great quack was discovered dressed in Oriental garb. The actress's head was first enveloped in a cloud of cashmere, and she was told to inhale the contents of a tube. She did so, and in a moment fainted away, being nearly suffocated. The quack became alarmed, and had to send for a *bona fide* medical man, who revived the victim. The actress went home in a cab, and found that, besides being incapacitated from singing, she was hardly able to speak, and had to cancel her engagement. She has consequently brought an action against the pseudo-native of Beloochistan, who had simply made her inhale a concoction which contained a large quantity of chloroform. Sahib Pitchitchine is also to be proceeded against by the *Parquet* for the illegal practice of medicine, and for having worn dazzling decorations to which he had no right."

The American Public Health Association will hold its fifteenth annual meeting at Memphis, Tenn., on Tuesday, Wednesday, Thursday, and Friday, November 8, 9, 10, and 11, 1887. Dr. G. B. Thornton, of Memphis, Tenn., is Chairman of the Local Committee of Arrangements.

Short-hand and the Study of Medicine.—A good deal has been said of late about short-hand and its usefulness to students and practitioners of medicine. The Short-hand Congress recently held in London, at which Dr. Gowers delivered an interesting address, opened up the subject. We regard the advice which has appeared in several of our English contemporaries, viz., that medical students will do well to study short-hand, as very unwise. Short-hand is a difficult and tedious art to acquire, and some can never learn it well. Unless it is learned well it is of no use. We should never advise anyone to learn short-hand unless they have some specific end, such as journalism, reporting, etc., in view.

Princely Measles.—It is pleasant to learn that the various princelets and princesses of Wales are suffering from only a mild attack of measles and that the prognosis is favorable.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PRACTICE OF MEDICINE.

Stated Meeting, October 18, 1887

CHARLES L. DANA, M.D., CHAIRMAN

THE Memorial Committee, consisting of Drs. A. Jacobi, T. H. Burchard, and R. C. M. Page, presented its report on the death ot the late

E. DARWIN HUDSON, M.D.,

which was read and accepted.

DR. GEORGE B. FOWLER then read a paper with the title

"THE DETECTION AND SIGNIFICANCE OF TRACES OF SUGAR IN THE URINE, WITH SPECIAL REFERENCE TO LIFE INSURANCE."

The interest in the paper centred in the statements that normal urine contains no sugar; that when normal urine reduces cupric oxide, or responds to the picric-acid test, the results are due to *uric acid* one-fourth, and *creatinine* three-fourths; that uric acid and creatinine were the reducing substances in normal urine had been established by Dr. George S. Johnson, whose experiments Dr. Fowler had repeated carefully, and was able to confirm them.

The discussion was opened by DR. A. JACOBI, who said that seven per cent. of sugar in the urine was the highest he had seen, and he wished to ask Dr. Fowler if it was correct that fifteen per cent. was not an infrequent occurrence.

DR. FOWLER replied that he saw a patient this evening whose urine contained fifteen per cent. of sugar, and from his reading he was quite certain that ten or twelve and fifteen per cent. was not infrequent. Human blood never contains more than one per cent. of sugar under any circumstances.

DR. JACOBI also had been of the opinion that uric acid and creatinine had been regarded as the reducing substances some time before Dr. Johnson's experiments. He believed that Dr. Fowler was right when he said that normal urine did not contain sugar. Practically, there were numerous causes of and conditions in which sugar was found in the urine. It was a common experience to find sugar in the urine when least expected. In the following conditions it might be expected, namely, in the urine of nursing women about the time of weaning. Then it was *milk* sugar, and milk sugar was also frequently found in the urine of the nursling. Further, it was found in a large number of diseases of the nervous system. Thus it was that either glycosuria or diabetes might occur with cerebral hemorrhage, tumors of the brain, etc., located even at a distance from the fourth ventricle. Sugar was also present in the urine in obstinate neuralgias, and in cases of persistent sciatica he always examined the urine with reference to its presence. He differentiates between glycosuria and diabetes. Glycosuria might depend upon indigestion, torpid liver, etc., and in those cases the Carlsbad waters would be serviceable, also the sulphate of soda, and especially the salicylate of soda. Purging would never do good in lean, exhausted diabetics, true diabetes being characterized by fatigue and emaciation.

DR. CHARLES A. DOREMUS spoke of a recent test consisting of equal parts of an alcoholic solution of thymol and strong sulphuric acid, to which saccharine urine was added, and produced a deep-red color. He believed that a very common error in the application of the Trommer and Fehling tests was

OVERHEATING THE CUPRIC SOLUTION.

This method was to heat the solution gently and only moderately in a water-bath, and, after the urine had been added, to set the test tube aside and allow it to stand for twenty-four hours. Uric acid is especially liable to reduce the cupric oxide in an overheated solution.

As to the fermentation test he preferred Roberts' test, and had discarded Einhorn's. He believed that all gaseous tests were unreliable for quantitative analysis for sugar. It was also possible to mistake milk sugar for glucose. No reliance could be placed on the specific gravity with reference to the presence of sugar in the urine, for the specific gravity was affected more by the saline constituents than by sugar. If the salts were doubled the specific gravity would be greatly increased, whereas it would not be increased nearly so much when the same quantity of sugar was added.

DR. EDWARD S. PECK said that the delicate tests for sugar in the urine did not play a practical part in examinations for life insurance. It was probable that Fehling's test was the most reliable for practical purposes. The position of medical attendant and that of medical examiner in a life insurance company were entirely different, and the significance of sugar in the urine was not an easy question to answer, in very many cases, so numerous were the causes by which glycosuria could be produced.

DR. KINNICUTT said that, while accepting Seegen's conclusions from his comprehensive and careful investigations, that the excretion of sugar by the urine was never a physiological function, that sugar was not present in *normal* urine, continued experience demonstrated the fact of its frequent occurrence in many and various *pathological* conditions. Disturbances of the abdominal circulation, in whatever way produced, are particularly prone to cause this symptom; a temporary gouty glycosuria is also well recognized. He would emphasize the fact, mentioned by Dr. Jacobi, of its frequent occurrence in nursing women, not only at the time of weaning, but with the existence of any obstruction to the flow from the lacteal gland. Not only in the graver neuroses may glycosuria be present, but also temporarily in the milder forms. Within the past year, he had found in the urine passed during apparently a purely hysterical attack sugar to the amount of twenty grains to the ounce. In this case, although the urine was examined daily in hospital for the subsequent three months, no trace of sugar was again detected. He was under the impression that the demonstration of the power of creatinine to sometimes prevent the precipitation of the oxide of copper in saccharine urine was of recent date, although this fact had been suspected for a number of years, such a suggestion having been made by Winogradoff, and, later, by Lauder Brunton.

DR. A. A. SMITH asked Dr. Fowler if life insurance companies declined to accept every applicant whose urine contained a trace of sugar, barring exceptional and well-known passing events.

DR. FOWLER said that were he a medical examiner he should decline to accept such applicants until he had either communicated with the medical attendant, or examined the applicant in the capacity of medical attendant.

DR. SMITH said it seemed to him that the presence of a trace of sugar in the urine did not have the same import that it seemed to have had a number of years ago. It certainly would be interesting, from the standpoint of the general practitioner, to know to what extent the presence of a trace of sugar in the urine shortened life. He recalled several cases in which a trace of sugar had been in the urine for twenty and thirty years, and the persons had been apparently healthy and able to perform the duties of their several occupations without inconvenience.

The question of prognosis in many of these cases was a very perplexing one.

Dr. Laurence Johnson had separated all the constituents of normal urine, and tested each one, and not one responded to the picric acid. What it was that produced the color he was unable to say, but he was certain that it was not creatinine. For delicate purposes he believed that the picric-acid test was entirely unreliable, and for glucose he had depended upon Fehling's test. He regarded Einhorn's instrument as unreliable.

Dr. W. H. Thomson spoke of the unreliability of the fermentation test, because the yeast was liable to contain starch granules. Fehling's solution, made according to the Guy's Hospital formula, recommended itself to general practitioners. He regarded

GLYCOSURIA AS A FUNCTIONAL NERVOUS DISEASE.

Diabetes was a true constitutional affection. He regarded it as perhaps more important to ascertain the proportion of urea in the urine, than the presence of sugar in moderate quantities.

Dr. Jacobi could not share with Dr. Thomson in the belief that glycosuria was a functional nervous disease. The digestive disorders to which he alluded were those which were not of nervous origin, but the result of chronic gastric catarrh, frequently complicated with chronic constipation, enlargement of the transverse colon particularly. Such cases could not be called cases of nervous disease, because we had to deal with local disorders of the large abdominal viscera. Sometimes, in such cases, the sugar would disappear or diminish in quantity after a drastic purge, and it was in such cases that the sulphate of soda and the salicylate of soda were beneficial.

Dr. Thomson said that he referred to those cases in which transient glycosuria accompanied lesions of different parts of the nervous system, such as contusion of the head, injuries of the spine, perhaps as low down as the tenth dorsal vertebra, sciatica, etc. But the prominent fact in these cases was that the glycosuria was transient. Diabetes was characterized by something more than glycosuria.

Dr. N. E. Brill remarked that the present tendency was not to differentiate between glycosuria and diabetes. In the abdominal cases spoken of by Dr. Jacobi there was irritation, which was conducted to the medulla from which the vaso-motor apparatus governing the circulation was influenced, and the result was glycosuria, in consequence of vaso-motor disturbances.

The Chairman thought the discussion had shown that an attempt to recognize in these affections two distinct diseases would, at present, result in much confusion. Although the distinctions mentioned by Dr. Jacobi might be of clinical importance, yet, when the finer points were traced, we should get hopelessly at sea. There were some cases of diabetes which could not be distinguished from glycosuria, and the fact of transiency was not admitted as an essential feature of glycosuria, the same as sugar was not always present persistently in diabetes.

With regard to

SUGAR IN THE URINE IN NEUROSES

he had found that it was present in about five per cent. in 100 cases of functional nervous disorders, excluding chorea and epilepsy, and including hysteria and neurasthenia.

Dr. Fowler, in closing the discussion, said that there seemed to be a general agreement with regard to the importance of recognizing small quantities of sugar in the urine; and the object of his paper was to direct attention to the means by which slight traces could be detected. He read a letter received from one of the largest life insurance companies in the world, in which it was stated that they regarded slight traces of sugar in the urine as of no pathological significance.

The Section then adjourned.

SECTION IN SURGERY.

Stated Meeting, October 10, 1887.

Robert F. Weir, M.D., Chairman.

NEPHROLITHOTOMY.

The Chairman presented an oxalate-of-lime calculus, weighing six grammes, which he removed through an incision in the right loin of a male patient, thirty-eight years of age, who, early in December, 1866, was suddenly seized with pain in the right side, attended by chills and fever, and followed by emaciation and a small quantity of pus in the urine. He entered the New York Hospital early in January, 1887, where an aspirator needle was thrust into a tumor on the right side, and gave exit to a small quantity of pus. The tumor was about the size of the fœtal head, and was very tender. It was regarded as an abscess of the kidney or of the cellular tissue around it. An incision was made in the loin, the kidney was reached, and then the aspirator needle was passed in again, and pus evacuated. The puncture was then enlarged with a bistoury, and a pint and a half of pus escaped. Two large drainage-tubes were inserted, antiseptic dressings were applied and changed frequently, and the patient progressed satisfactorily. Exploration for stone was not attempted at that time, nor was the abscess cavity washed out, as the evidence was not absolute that it was a nephritic abscess. The man gained in weight, and got about slowly. About the 12th of May he had so far recovered as to leave the hospital. Not long afterward he reported that the wound was discharging a fluid that had a urinous odor, so Dr. Weir explored the sinus and obtained a distinct "click," as the long bent probe touched the calculus. The patient was at once returned to the hospital, where the stone presented was extracted. The urine immediately after the operation became more plenteous and purulent, but soon began to improve in appearance; and the patient, although he was not yet well (the sinus having not yet healed entirely), was on the way to complete recovery. (The patient was presented.) The kidney substance had contracted to one-quarter its size at the time of the opening of the abscess, and was still diminishing. With the extraction of the stone the quantity of urine discharged through the opening in the loin decreased.

The urine now is nearly normal. If nephrectomy finally became necessary, Dr. Weir believed that the chances for recovery from that operation had been greatly improved by what had already been done.

DUPUYTREN'S CONTRACTION—REMOVAL OF THE BAND.

Dr. Abbe presented the band which had produced the contraction in a case of this deformity. The contraction affected the left ring-finger, which was lying in the palm. Adams' method of treatment, by making multiple subcutaneous divisions, had not given him as satisfactory results as free, open incision, dissecting out the band of glistening fibrous tissue, and dressing the wound antiseptically with horse-hair drainage.

After the operation he does not place the hand upon a splint at once, which he regarded as important. At the end of a week or ten days, extension could be made by means of a posterior splint. In some cases there will be slight stiffness at the end of a year, but ultimately the finger becomes free.

The time required for the dissection was at least half an hour. He believed that drainage was advantageous even in as small a wound as this, for the reason that when the palm was united there was a disposition for all the skin to peel off. If the skin of the palm could be put in the best possible condition by macerating the hand for two days, and for twenty-four hours immediately preceding the operation, enveloping it in cloth dampened with bichloride solution, probably good vascularity would be obtained for prompt union of the wound. Then, if drained, light pressure would answer all purposes for hold-

ing the edges in proper coaptation. The band was not attached to either the bone or tendon, although it might grasp the sheath of the tendon, and at the upper part was attached to the dense aponeurosis of the palmar fascia.

Dr. Gibney asked Dr. Abbe if his cases had shown any disposition to relapse.

Dr. Abbe said that he could not say so much for this operation as for Adams' on that point, as those cases which he had been able to keep under observation had done admirably. The special advantage of this operation was to get rid of the adventitious tissue.

The Chairman asked Dr. Abbe if there was not more inflammatory reaction in his cases after Adams' operation than after this more heroic method.

Dr. Abbe replied that there was, but he thought it was because he had put the band upon an extension splint at once.

The Chairman had removed the cicatricial band after burns with good results, and he also spoke of the benefit of drainage.

Dr. A. M. Phelps presented several

CASTS ILLUSTRATING CASES

of Dupuytren's contraction, before and after the operation. He believed that in the milder forms of the deformity the open operation was not warranted. He also believed that Adams' operation was not properly performed in many cases; that when properly performed excellent results could be obtained.

Dr. C. A. Powers read a paper on

FRACTURES THROUGH THE HEAD OF THE RADIUS,

in which he gave a *résumé* of the literature of this rare injury, together with a brief outline of the history of the reported cases, and one which had been under his own care. At the close of his paper the writer raised the question of the propriety of removing the fragment of the head of the bone by an operation.

The Chairman could not recall a single case of this fracture. With regard to removal of the piece of bone, he believed that conservative treatment was the best. Replace the parts as well as possible, and wait for time to determine the results. If at the end of one year the function of the elbow was seriously impaired, then the question might arise whether or not exsection should be performed. He also spoke of the aid offered by fomentations in limbering stiffened joints after fractures.

Dr. R. T. Morris refused, in one case of comminuted fracture of the head of the humerus, to perform primary exsection, and at the end of a year there was fairly good movement and union of the fragments.

Dr. Abbe spoke of the importance of maintaining absolute rest during the first week, as a single movement of the joint might separate the parts, and result in fibrinous union.

Dr. Judson was unable to see how poultices applied to the joint could effect the desired relaxation mentioned by the writer of the paper.

Dr. J. H. Girdner gave a brief *résumé* of some experiments he had performed, which demonstrated that hot water, 120° to 130° F., applied several consecutive hours to the shaven leg of a dog, reduced to a very marked degree the quantity of blood that the limb contained, and at the same time made the tissues softer and less resilient than those of the untreated leg. The late Dr. Frank H. Hamilton applied hot water freely in all cases of stiffness of joints after fractures, and with good effects. To accomplish the desired end, *hot* and not warm water must be used.

Dr. A. Jacobi referred to physiological experiments performed by Heidenhain, of Breslau, in which it was shown that the direct result of the application of heat externally was reduction of internal temperature. The immediate effect upon the superficial vessels was to dilate them, but with regard to the deeper tissues the effect was different.

PASSIVE MOTION AFTER FRACTURES.

Dr. Powers said, concerning the value of rest, that he was aware that most of the text-books taught that passive motion should be resorted to early, but he believed that in all cases of fracture involving the elbow, the part should be kept at rest for four weeks. Movements before that time had elapsed were positively vicious, and excited inflammation.

Dr. A. M. Phelps did not approve of long-continued rest in cases of fracture near or into joints. Passive motion should be applied ten days after the injury. After two or three weeks he would apply hot water, use friction, and employ compression by means of a bandage.

Dr. Gibney advocated four weeks of absolute rest. If passive motion was commenced a week or ten days after the injury, adhesions were more likely to occur than when the limb was left entirely alone. The joint should not be interfered with as early as ten days, and when motion was applied, active was better than passive.

Dr. Girdner said that there need be no fear of anchylosis following fracture involving joints; but he believed it to be dangerous to allow a broken joint to remain unmoved for three or four weeks, and no man should do it.

Dr. Abbe remarked that the result of the discussion of this question in the New York Surgical Society was that the majority were emphatically in favor of leaving the limb at rest, and that when anchylosis took place it was due to faulty replacement of the fragments.

The Section then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 14, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

Dr. J. S. Thacher, from the Committee on Microscopy, reported on the specimen presented by Dr. A. P. Dudley on June 8, 1887: The walls of the blood-vessels are thickened and hyaline, as is so often the case in the ovaries of adults. There are also several minute cysts present. No other lesions were found.

Dr. Frank Ferguson exhibited under the microscope a specimen which showed

THE HOOKLETS OF THE ECHINOCOCCUS,

found in the fluid from a cyst of the liver of a patient who was a resident of Cuba.

Dr. Ferguson also presented a specimen of

TUBERCULOSIS OF THE BRAIN.

The lesion showed itself in large nodules scattered through the substance of the brain. Microscopical examination had revealed tubercle-bacilli in these nodules. There were miliary tubercles in the upper part of the left lung. There was tuberculosis of the bones of the skull and of the scapula, and tubercles were found in other parts of the body. The patient was a child with the history of vaccination a short time previous to the development of tubercular disease, and the question had been raised whether tubercular virus had been introduced by vaccination.

Dr. W. P. Northrup regarded the tubercular nodules in the brain as very extraordinary. In only two or three cases had he seen them of such size in the substance of the brain. Less than a year ago he presented a similar specimen to the Society, and regarded it as quite rare.

Dr. J. S. Thacher presented a specimen of large

PERI-URETHRAL ABSCESS,

portions of which could be seen in the prostate. There was chronic cystitis, and the walls of the bladder were much hypertrophied. One ureter was very much dilated, its walls were thickened, and the mucous membrane congested; one kidney showed the lesions of

suppurative nephritis. There were also pyelitis and dilatation of the pelvis of the same kidney, and in certain parts evidence of diphtheritic inflammation, shown by a patch of yellowish pseudo-membrane so closely adherent that when torn off a raw surface of the underlying tissue remained. All that the patient complained of was a certain amount of pain in the lumbar region, some about the bladder, and incontinence of urine. There was no stricture.

Dr. H. J. Boldt presented a specimen that showed

LOBAR PNEUMONIA—ABSCESS—GANGRENE—TUBERCULOSIS.

The patient was a man who had been taken sick, about six weeks ago, with what was diagnosticated as lobar pneumonia at the apex of the right lung. At the time Dr. Boldt saw the patient the question arose, on account of the profuse fetid expectoration, whether or not abscess was present as a complication. The microscopic examination of the expectoration by Dr. Heitzmann rather confirmed that diagnosis. There was no elevation of temperature above 99° F. The surface of the lung was studded with miliary tubercles, and there was beginning gangrene in the walls of the abscess.

Dr. W. P. Northrup presented a specimen sent to him by Dr. Morgan, of Ithaca, N. Y., which was referred to the Committee on Microscopy. It was accompanied by the following history:

CONGENITAL ABSENCE OF THE RIGHT KIDNEY—CARCINOMA OF THE LIVER, COMMON BILE-DUCT, AND HEAD OF THE PANCREAS—CARCINOMATOUS ULCERS OF THE FUNDUS OF THE BLADDER, WITH HÆMATURIA.

The patient was a man, seventy-six years of age, who had been under Dr. E. J. Morgan's observation for several years. Eighteen months before death he began to lose flesh, appetite, and strength. Six months before death he passed from the bladder, once or twice, clear, fluid, bright blood in considerable quantities. The patient felt better after the hemorrhage. Three months before death he again passed blood from the bladder occasionally, the amount varying, and then he seemed prostrated by the loss of blood.

The symptoms which led to diagnosis were progressive emaciation, loss of strength, and hæmaturia. About one month before death, when emaciation was extreme, a tumor, apparently as large as a large orange, was discovered to the right of, and on a level with, the umbilicus. It was firm, ovoid, and movable. The liver was markedly enlarged. There was no jaundice. The countenance was sallow and cachectic. At last there was diarrhœa and occasional vomiting, stupor and transient coma, followed by exhaustion and death.

Autopsy was made, thirty-six hours later, by Dr. Lewis, in presence of Drs. Morgan, Hunter, Turnbull, Baker, and Northrup. The body was extremely emaciated. The liver was enlarged to twice its normal size, its surface was nodular, and the centres of the nodules were softened. The blood-vessels of the surface were dilated and radiating from the centres of the nodules. The common bile-duct was half an inch thick and carcinomatous. The head of the pancreas was involved, and formed the tumor felt through the abdominal wall. The tumor thus formed was three and a half inches long, two and a half inches wide, was freely movable, and of firm consistence. In its centre it was softened, but not diffluent, except just at the junction of the bile-duct with the intestine, where it had found exit into the gut by means of numerous small perforations about the papilla of the bile-duct.

The interesting pathological feature was found in the bladder. The prostate was enlarged, but this was of no pathological significance. The vesical mucous membrane was normal in general appearance at the base and upon the lower half of the anterior wall. Upon the remaining wall there were from fifty to one hundred circular, punched-out ulcers, varying in diameter from five to fifty millimetres. These were clean-cut, free from slough, redder than the mucous membrane surrounding them, and extended through the mucous membrane and half through the somewhat thickened bladder-wall. These ulcers were considered the source of the hæmaturia.

The left kidney was perfectly healthy, was nearly twice the ordinary adult size, and with the exception of three small cysts was normal. The ureter and urethra were also free from lesion. There was congenital absence of the right kidney. A rudimentary ureter could be traced a few inches from the bladder, but there was lost in the tissues.

Dr. Morgon had known this patient as a healthy man for twenty years. There was no history of hereditary predisposition to cancer.

Dr. Northrup referred to cases in which bright fluid blood had been passed in considerable quantities from the bladder without known cause, and the hæmaturia had not recurred.

Dr. Waldstein recalled two cases of hæmaturia, although they had no direct analogy with the case under consideration.

The first patient was an apparently healthy woman, who, without known cause, except there was reason to suppose that she had caught cold, passed a large quantity of blood from the bladder. Without treatment, the patient had no recurrence of the hæmaturia.

On looking up the literature at that time, he found that hæmaturia might be due simply to the effect of cold. As an experiment, he ordered that her feet be placed in ice-cold water, which was done, and she had another attack of hæmaturia.

The other was a case which occurred in the practice of a physician in Berlin. On examination, peculiar bodies were found in the urine, which were presented to Virchow, who declared them to be a parasite which he had described many years before in connection with a similar case, and to which he gave the name *rhabditis*.

Dr. Wyeth said that

HÆMATURIA

was not an uncommon occurrence in surgical practice. He had reported to the Society, three or four years ago, a case of obscure hemorrhage from the bladder, in which, on careful microscopical examination of the fluid discharged, he found the eggs of the parasite *Bilharzia hæmatobia*. The patient was a young man who went out as a missionary to Africa, where, especially along the Eastern coast, the affection caused by this parasite is very common.

About a year ago he was called to see a woman who, while coming from St. Louis, took cold and had a discharge of blood from the urethra that caused her great alarm.

The third case was one in which he removed the right kidney of a woman thirty-eight years of age. There was recurrent hæmaturia. Dr. Janeway diagnosticated neoplasm as the cause, and the operation proved the diagnosis to be correct. The symptom of pain was very much like that in the case reported by Dr. Northrup.

Dr. Mary Dixon Jones presented two specimens of

THE UTERUS REMOVED FOR MALIGNANT DISEASE.

Dr. Jones also presented two specimens of

OVARIES AND TUBES REMOVED BY LAPAROTOMY,

accompanied by microscopic sections.

Dr. Boldt thought Dr. Jones was in error in saying that Dr. Martin considered vaginal hysterectomy a difficult operation. For in any case where the uterus is mobile it is an easy operation, and one completely free from danger.

Dr. Jones said that her quotation was taken directly from Dr. Fenger's article on this subject.

The Society then went into executive session.

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Sixteenth Annual Session, held in Toulouse, September 22 to 29, 1887.

(Special Report to THE MEDICAL RECORD.)

(Continued from page 580.)

TUESDAY, SEPTEMBER 27TH—FOURTH DAY.

DR. E. MAUREL then read a paper giving the results of some microscopical researches concerning

THE PARASITIC NATURE OF MALARIA.

The speaker thought that it was always easy to distinguish a healthy from a malarial soil. In the air taken from malarious districts there were always numerous micro-organisms, some of which were possibly Laveran's corpuscles in an early stage of their development. He then discussed the question of the rôle played by Laveran's corpuscles in the production of malaria, and said that he believed they were intimately concerned in the etiology of the affection, although there was still room for doubt.

DR. DE MUSGRAVE-CLAY read a paper on the connection between

HOUSE-MOVING AND INFECTIOUS DISEASES.

He said that he had several times noticed the occurrence of isolated cases of disease after the subsidence of an epidemic, and in his search after the cause had found it, he believed, in the fact that either the family in which the disease occurred, or one of the neighbors, had recently moved. He thought it likely that the act of moving had, by taking up the carpets, etc., made a dust and had thus caused a fresh distribution of the infectious germs. He reported three cases of this nature, and said that his object was to call the attention of his confrères to the possibility of such an occurrence, and also to furnish another proof of the necessity of thorough disinfection of every place in which there had been even a single case of contagious disease.

DR. MAUREL then presented a communication on the

RETRO-STERNAL PULSE.

By this term he meant the pulsation that can be felt by pressing firmly downward behind the supra-sternal notch. He had studied this pulse in five hundred individuals, three hundred of whom were ill from various diseases. This pulse is more commonly felt in those who are the subjects of some disease, though it may be present in a perfectly healthy person. He thought that the pulse was due to the pulsations of the vessels springing from the arch of the aorta, transmitted through the trunk of the left brachio-cephalic vein. This pulse is found almost constantly in cardiac diseases and in typhoid fever. When present in healthy persons this pulse must be due to some peculiar anatomical condition. In disease it may be explained by (*a*) a raising of the brachio-cephalic trunk; (*b*) a dilatation of the vessel from obstructed return circulation; (*c*) a passive dilatation from loss of tone in the wall of the vessel; (*d*) insufficiency of the tricuspid valve. The speaker believed that this symptom might be of great utility in both diagnosis and prognosis in certain diseases.

DR. OLLIER followed with a paper on

RESECTION OF THE KNEE

and the simplification of its after-treatment. He endeavored always to preserve the lateral ligaments of the joint, and used every precaution to obtain perfect antisepsis in order to avoid frequent change of dressings. In nine out of ten of his cases of resection of the knee, he had not been obliged to remove the dressing until the fiftieth day, and never had occasion to regret his delay in so doing. He was an earnest advocate of iodoform, in spite of the recent doubts which had been cast upon its utility, and always made very liberal use of it.

WEDNESDAY, SEPTEMBER 28TH—FIFTH DAY.

DR. ARNOZAN presented a paper upon the relations between

CUTANEOUS LESIONS OF THE NOSE AND AFFECTIONS OF THE NASAL FOSSÆ.

The speaker said that the cutaneous affections of the nose, especially of the tip and alæ, were often extremely rebellious to treatment. It was the habit to refer these lesions to distant affections—dyspepsia and the like—but he thought that their relation to deep affections of the nasal fossæ was too little appreciated. He reported two cases in which this relation seemed evident, and he thought the physician should never neglect to explore the nasal fossæ when called upon to treat cutaneous lesions of the nose.

DR. HUCHARD then presented a communication upon the relations of

SUBACUTE ARTERIO-SCLEROSIS AND VASCULAR SPASM.

All the causes, excepting senility, which were capable of producing this condition (alcoholism, overwork, etc.) excited first an increase of arterial tension. The proper treatment, therefore, consisted in the administration of remedies to reduce this arterial tension, and the avoidance of such as would cause it. In the latter class of drugs were digitalis, ergot, and belladonna, and in the former were the iodides, nitrites, and nitroglycerine. The remedy which he preferred in all these cases was nitroglycerine.

DRS. PÉAN and SECHEYRON presented a paper on

HYDATID CYSTS OF THE UTERUS.

These cysts might be interstitial or submucous. The occurrence of pregnancy usually caused them to increase rapidly in size, though their influence upon the course of pregnancy seemed to be *nil*. When present they were a potent cause of dystocia. The treatment consisted in puncture and drainage.

DR. ANDRÉ followed with a paper on the

CONDITION OF THE LIVER IN CHLOROSIS.

He had found that there was always a temporary atrophy of this organ in chlorosis, and the lesson that he drew from this was that the liver should be stimulated by hydrotherapy, electricity, and hepatic remedies.

DRS. LIVON and ALEZAIS presented a communication upon the

CONDITION OF THE URINE IN TABES DORSALIS.

The following were their conclusions: 1. There is a tendency to a diminution in the quantity of urea excreted in the twenty-four hours. 2. There is a diminution in the free phosphoric acid, and a proportional increase in the phosphates. 3. There is a considerable variation in the amount of chlorides, with a general tendency to increase.

DR. BERNHEIM related a case of

LINGUAL MONOHEMIPLEGIA

with cortical localization. The patient, a girl twenty-three years of age, suffering from multiple sarcomatous tumors, was attacked by paralysis of the right half of the tongue, but without any other evidences of facial hemiplegia. After death a lesion was found along the lower border of the inferior extremity of the left ascending frontal convolution, at its anterior aspect, six millimetres behind the fissure separating it from the third frontal convolution.

DR. VOISIN related two cases of

ONANISM IN YOUNG GIRLS

successfully treated by hypnotic suggestion.

DR. CHARAZAC reported a case of spontaneous expulsion of a

LARYNGEAL POLYPUS.

The patient, a woman thirty-one years of age, had suffered from the presence of the polypus for three years,

and had lost her voice in consequence. One day, during a violent fit of coughing, she expelled a fleshy mass which was seen to be the polypus. Complete recovery ensued.

Dr. Pamard related two cases of

SUBPERIOSTEAL RESECTION OF THE ELBOW.

In both instances the patients recovered, with perfect movement of the articulation.

Dr. Petit read a paper on the

TREATMENT OF EPISTAXIS BY COUNTER-IRRITATION OVER THE LIVER.

He recalled the observations of M. Verneuil on this subject, and gave a brief report of several interesting cases in which a rebellious epistaxis was promptly relieved by vesication over the hepatic region.

Dr. Montaz reported a case of

TUBERCULAR EPIDIDYMITIS

which had supervened upon a gonorrhœal inflammation of the same parts.

Dr. Terson called the attention of the members of the Association to the fact that the Toulouse Medical Society had chosen as the subject for the Gaussail prize for 1889 the question of the

OCULAR LESIONS DUE TO SYPHILIS, AND THEIR TREATMENT.

The subject was a very important one, and was not yet exhausted by any means.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HARVEIAN ORATION—OPENING MEETINGS OF THE MEDICAL SOCIETIES—THE FEMALE PELVIS AND THE CAUSE OF ITS DIFFERENCES FROM THAT OF THE MALE—ARSENIC AND PIGMENTATION—PULMONARY REGURGITATION—THE PSYCHOLOGY OF JOKING—ITEMS OF NEWS.

London, October 19, 1887.

The Annual Harveian Oration at the College of Physicians was delivered yesterday by Dr. Stone, one of the Censors. Sir William Jenner occupied the chair, and there was a good attendance. After referring to Harvey's own lectures and to the autotype transcript of them recently published, the lecturer went on to sketch the character of Harvey as a scholar, a lecturer, a physicist, and a man of genial and humorous disposition. He remarked that it was singular how much of Harvey's Twelve Rules or "Canones Anatomiæ Generalis" was still valuable. Harvey's great discovery was essentially of a physical or mechanical nature. This was proved by his own words and by his division of anatomy into three parts, "philosophica, medica, mechanica." Dr. S one—himself a physicist—maintained that physics is neglected in the study of medicine, and urged that a course of physiological physics would be a real boon to all students of medicine. Such a course would eminently fulfil the exact purpose of the great man whom they had that day met to commemorate. After the oration the Baly Gold Medal (Biennial) was awarded to Dr. David Ferrier for his physiological researches on the nervous system.

The societies are beginning their winter campaign. The Obstetrical Society was the first in the field. The first paper read was one by Mr. Arbuthnot Lane, Demonstrator of Anatomy at Guy's Hospital, and was devoted to a consideration of the question of what are the chief factors which determine the differences which exist in the form of the male and female pelves. Mr. Lane criticised the theory that most of the differences are due to force exerted by the femora and sacrum upon the innominate bones. He considered the conditions of the thorax and pelvis as exactly analogous in the two sexes. He regarded the male thorax as the original type, and considered that the altered form of the female thorax was determined by the additional function performed by it, of accommodating the fœtus during the later months of pregnancy. The female pelvis performed one function in addition to that performed by the male pelvis, viz., the support and transmission of the fœtus, and he regarded this as the sole factor which determined the variations in form of the pelvis in the two sexes. Mr. Lane urged that there was a fallacy in arguing from the manner in which certain forces produced changes in the pelves of diseased females during the lifetime of a single individual, that the same forces acting upon a healthy female determined that peculiarity in the form of the pelvis. He considered that the pressure exerted by the fœtus, represented as a developmental factor, prevented the occurrence of such variations in the female subject as occurred in the male.

In conclusion, Mr. Lane maintained that this pressure was the sole determining factor of the variations in the form of the male and female pelves. Mr. Lane's views, although ingeniously put forward, were by no means received without question, but excited a considerable amount of hostile criticism. Dr. Herman said he agreed with Mr. Lane in holding that the form of the pelvis was due to inheritance—to influences acting on many generations of ancestors; but he thought the way in which the shape of the pelvis was modified in transmission through many generations was mainly this: Women with well-shaped pelves were able to bear large, strong children, likely to survive, and to inherit and transmit that type of pelvis. He could not agree with Mr. Lane that the pressure of the head during labor modified the shape of the pelvis. This stage on the average lasted less than two hours. So brief and intermittent a pressure exerted on fully ossified bones could not have any influence. Both Dr. Playfair and Dr. Galabin remarked that the peculiarities of the female pelvis had been generally ascribed to the forces of development or the presence of genital organs in the pelvis. Dr. Champneys remarked that the effect of pressure on respiration could not begin before the sixth month, which left three months in each pregnancy, or thirty months in ten pregnancies, and against this we had to put the remainder of a lifetime. The production of alterations in the skeleton during pregnancy was one thing, and the alteration of the skeleton by laborious occupations was quite another. Several other papers were read.

At the Clinical Society, on Friday last, three papers were read. Two of these provoked some little discussion. One was by Dr. Handford, on a case of pemphigus in a child. Arsenical treatment was employed, but was followed by pigmentation, so it was stopped, and the patient treated by wet packing. In a month the skin had resumed its normal appearance and much of the pigmentation had disappeared, but on the hands and feet were many patches of cicatricial-looking skin, thickened and elevated. They were covered with white points, and resembled (to the naked eye) miliary tubercles, but they consisted of accumulations of degenerating epithelial cells in the deeper parts of the epidermis. They disappeared in four or five months. Dr. Crocker remarked that pigmentation from the use of arsenic was fairly common on the site of eruption, and general pigmentation also occurred from time to time, though it was less common. Sir Dyce Duckworth spoke of the value of arsenic in cases of pemphigus. Sir Dyce Duckworth then read a paper on a case of pulmonary arterial reflux. The lesion was not diagnosed during life. The President (Dr. Broadbent) remarked that pulmonary regurgitation was so very rare that this was quite excusable. He had himself seen ten cases which had been diagnosed as pulmonary regurgitation, but he had not been enabled to verify his diagnosis. Dr. Douglas Powell remarked that

he had not been able to examine post mortem any of the few cases of pulmonary regurgitation which he had himself seen.

The first meeting of the Medical Society of London took place on Monday evening, when there was a large attendance. Considerable interest was excited by the address of the President (Dr. Hughlings-Jackson). He took for his subject "The Psychology of Joking." Dr. Jackson maintained that punning was entitled to a better position in the intellectual world than was generally accorded to it, though it was really a morbid condition, viz., a mental diplopia. The mere conception of humor was in itself an indication of a certain intellectual development. Humor in its various manifestations, and their relation to morbid mental states, were then dwelt on at some length. A vote of thanks to the President for his address was passed, and a paper on "Simple Dilatation of the Stomach" was then read by Dr. Clifford Allbutt, of Leeds.

Sir William Gull has been prostrated by an attack of paralysis while taking his autumnal holiday in Scotland.

Mr. Savory, President of the Royal College of Surgeons, has just been appointed Surgeon Extraordinary to Her Majesty the Queen.

The Metropolitan Free Hospital has adopted the pay principle for out-patients, and will henceforth be known as "The Metropolitan Hospital."

THE MORTALITY-RATE OF THE REGULAR AND HOMŒOPATHIC SERVICES IN COOK COUNTY HOSPITAL.

To the Editor of The Medical Record.

Sir: *À propos* of your editorial on the mortality-rate of the regular and homœopathic services in Cook County Hospital, the following must be remembered: 1. The homœopathic service has assigned to it only a fraction over one-fourth of all the patients; in 1885–86 the regulars treated 5.909 and the homœopaths 1,532. 2. The examining interne is a regular, and consequently the larger number of interesting and probably fatal cases go to the regular side. 3. Patients have their choice of treatment, and when very ill they naturally refuse to take homœopathic treatment. 4. The homœopaths, in severe cases, abandon their dilutions and resort to the same therapeutic measures as the regulars. In fact, there is no exclusively homœopathic practice in Cook County Hospital. 5. A large number of moribund cases are assigned to the regulars.

A Regular.

THE GERMICIDE PROPERTIES OF IODOFORM.

To the Editor of The Medical Record.

Sir: While in Stockholm, Sweden, my attention was directed to a review, in The Record, of the investigations made by Messrs. Heyn and Roving, of Copenhagen, Denmark, concerning the germicide properties of iodoform. These reports being negative, I reached that city prepared to see what has been an indispensable agent in the hands of nearly every surgeon thrown aside as utterly worthless. Yet, after a month's study of the many excellent methods employed in the hospitals of Copenhagen, I am prepared to say that nowhere have I seen such a free and unreserved use of iodoform.

Kommune Hospital, of eight hundred and twenty beds, with two large surgical wards, does not confirm the results obtained in laboratory by these two gentlemen. On the contrary, Professor Axel Iverson, in charge of one of the wards, has become so strong an advocate of its use that iodoform gauze has taken the place of nearly every other form of drainage. One rarely sees the bone or rubber drainage-tube in his service. He was especially prominent in its favor, and declared clinical experience in this case, at least, as vastly superior to experiments with gelatine. Professor Studegard employs it less frequently, simply because of its disagreeable odor. Professor Howitz, with his large gynecological experience in the Sisters' Hospital, and the female ward of Fredericksberg Hospital, employs it in nearly all of his surgical operations, and only with the best results. Since he began inserting an iodoform pencil into the cervical canal, in all—twelve, if I remember correctly—his hysterectomies, he has not had a single death. This he attributes solely to the use of iodoform, as he has in no way modified his operation. In so far as I could learn, not one of the hospitals had laid it aside, but are encouraged to continue its use. Whatever new light the future may reveal by further inquiries, certain it is that not one in a position to speak supports in any way the published report; and I am sure this is done in no spirit of opposition to any recently discovered truth, for though Denmark be small, it harbors no narrow or contracted ideas. They are keenly alive to accept anything new, if they do not even anticipate it.

J. G. Tapper.

Berlin, Germany, October 6, 1887.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 23 to October 29, 1887.

Greenleaf, Charles R., Major and Surgeon. Will proceed from this city to the places hereinafter named, in the order in which they are named, for the purpose of investigating the methods of examining recruits at the depots and rendezvous located thereat, and of instructing recruiting officers in matters pertaining to such examinations: Baltimore, Md.; Philadelphia, Pa.; Camden, N. J.; New York City and David's Island, N. Y.; Boston, Mass.; Portland, Me.; Albany and Buffalo, N. Y.; Cleveland, O.; Detroit, Mich.; Chicago, Ill.; Milwaukee, Wis.; St. Paul, Minn.; Jefferson Barracks and St. Louis, Mo.; Cincinnati and Columbus, O.; and Pittsburg, Pa. S. O. 248, A. G. O., October 25, 1887.

Cleary, P. J. A., Major and Surgeon. Ordered to proceed from Fort Huachuca to Fort McDowell, and report to the commanding officer for duty as Post Surgeon. S. O. 111, Department of Arizona, October 18, 1887.

Brown, Paul R., Captain and Assistant Surgeon. Leave of absence extended one month. S. O. 250, A. G. O., October 27, 1887.

Burton, H. G., Captain and Assistant Surgeon. Ordered from Plattsburg Barracks, N. Y., to Watervliet Arsenal, N. Y.

Merrill, J. C., Captain and Assistant Surgeon. Ordered from Watervliet Arsenal to Frankford Arsenal, Pa. S. O. 249, A. G. O., October 26, 1887.

Richard, Charles, Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect when his services can be spared by his post commander. S. O. 247, A. G. O., October 22, 1887.

Jarvis, Nathan S., First Lieutenant and Assistant Surgeon. Ordered for field duty in Department of the Platte. S. O. 246, A. G. O., October 21, 1887.

Jarvis, Nathan S., First Lieutenant and Assistant Surgeon. Ordered from Department of the Platte to Department of Missouri, for duty in the field. S. O. 249, A. G. O., October 26, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 29, 1887.

Bates, N. L., Medical Inspector. Ordered to hold himself in readiness for orders to the Trenton.

Hesler, F. A., Assistant Surgeon. Ordered to examination for promotion.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 29, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	25	11
Scarlet fever	55	13
Cerebro-spinal meningitis	6	4
Measles	17	2
Diphtheria	115	46
Small-pox	2	0
Yellow fever	0	0
Cholera	0	0

POISONING FROM ILLUMINATING GAS AND ITS TREATMENT.—Dr. Lamb, at a meeting of the Medical Society of the District of Columbia (*Journal of the American Medical Association*, September 3, 1887,) reported a case of death from illuminating gas, and has also studied 16 other cases found in medical literature. Of these 16 cases 10 were men, 6 women; 10 recovered, 6 died; the ages ranged from 22 to 82; of 4 the age was not stated, but, judging by the descriptions, it was probably between 20 and 50. Death occurred in 3 cases within a half-hour after exposure; in 2 cases in 11 hours; in 2 cases about 36 hours; in one case 50 hours. In that reported by Dr. Lamb, life was prolonged 8 days. The accident happened of course oftenest at night; exposure, usually beginning between 10 and 12 P.M., and ending between 6 and 9 A.M., averaging about 10 hours. The variable time at which death occurs after exposure is probably to be explained by different proportions of gas in the air. An examination of the signs noted by those who attended the sufferers at or soon after their release from exposure shows sufficient uniformity to enable us to fix upon some as characteristic. Stupor was most frequently noted, in 10 cases; and, in the absence of any statement to the contrary, was probably present in all. In studying reports of cases we often meet with a failure to note a sign or symptom which was nevertheless probably present. Next to stupor in frequency were noted coldness and pallor of the skin, stertorous and shallow breathing, odor of gas in the breath, dilatation of pupils, and rigidity. Occasionally it was stated that the face was swollen, skin was livid, skin was of normal heat, there was sweating, there was frothing at mouth, pupils were contracted, or one dilated and the other contracted, there was spasm of jaw, or even convulsion, pulse was regular, or small and weak, or not felt. Sometimes on removal of patient to the open air, the breathing became more difficult and there was an increase in rigidity especially shown by the spasm of the lower jaw. The treatment which appeared to be of most service was as follows: 1. The access of fresh air, obtained usually by opening windows and doors; preferably by removing the patient to a room distant from the poisoned air. In some cases the direct inhalation of *oxygen gas* has seemed to be of benefit; the two cases reported by Owen were thus treated and recovered. From a careful consideration of these cases, Dr. Lamb concluded that the recumbent position is the proper one in which to place the patient; not sitting, as some have attempted. In 3 cases artificial respiration was tried, but the patients died in spite of it. 2. Warmth. Fresh air furnishes the necessary oxygen to the blood; warmth favors the circulation and all other functions. Cold affusions were used in two cases; both died. 3. Diffusible stimulants, as brandy, whiskey, ammonia, by mouth, rectum, and hypodermically. The case which showed the most rapid recovery was one in which 15 drop doses of spirit of ammonia were given every few minutes. Faradization or galvanism was tried in several cases, which, however, died. Tickling the fauces in one case seemed to be beneficial; the effort at vomiting cleared the air-passages of frothy mucus, after which breathing improved. On the whole, then, the best treatment is to secure fresh air, and if possible pure oxygen; the recumbent position; warmth; diffusible stimulants; with such aids as artificial respiration, electricity, and nutrient enemata.

THE CHEMICAL TEST FOR THE CHOLERA-BACILLUS.—Dr. Alfred Meyer, of New York, writes: "Chemical tests for micro-organisms have a life-history as well as the micro-organisms which they are claimed to differentiate. In the issue of THE MEDICAL RECORD of October 1st you describe Bujwid's reaction of the cholera-bacilli with five to ten per cent. of muriatic acid, and quote his claim that the rose-violet color developed is a special characteristic of the comma-bacillus of Asiatic cholera, and distinguishes it sharply from other similar forms of bacteria. According to Charles H. Ali-Cohen, who publishes his observations in the *Fortschritte der Medicin* of September 1st, this color only appears if the acid employed in the test (whether sulphuric, muriatic, or nitric) contains some *nitrous acid*, and that the rapidity of its appearance is dependent, to a certain extent, upon the amount of HNO_2 present. Ali-Cohen also claims to have cultivated a bacillus from the spleen of typhoid-fever patients which gives exactly the same reaction with these acids. In view of this discovery, he would deny the assumption that the so-called cholera-red is distinctively characteristic of Koch's bacillus."

GALL-STONES.—Dr. R. H. Sabin, of West Troy, writes: "In the report of my paper on gall-stones, on page 495 of THE MEDICAL RECORD, there is a mistake. Where it reads 'alkaline' it should read 'an acid state of the urine.' In the case reported the woman had severe attacks of pain, and passed from the bowels, at the second or third movement after the pain, a quantity of what looked like sand, and when magnified presented the appearance of peanuts. Some thought they were seeds, others that they were gall-stones."

DECOCTION OF LEMON IN MALARIAL FEVER.—Dr. W. F. Morgan, of Leavenworth, Kan., writes that he has used the decoction of lemon in many cases of intermittent fever with excellent results. He has also employed it with benefit in remitting fevers, and, despite its apparent simplicity, has found no disposition on the part of his patients to treat it with indifference or neglect.

HERNIOTOMY UNDER COCAINE.—Dr. W. W. Hewlett, of Babylon, L. I., writes: "Since the publication of my case of herniotomy under cocaine-anæsthesia my attention has been called to the report of a similar case by Dr. A. F. Fuchs, of Fredonia, Wis., in THE MEDICAL RECORD of January 29, 1887. I therefore waive all claim to priority in this method of operating in strangulated hernia."

CRUEL METHODS OF VACCINATION.—Sir Joseph Hooker has written a letter to the London *Times*, in which he draws attention to the "heroic but cruel method" of vaccination now pursued, which he thinks has much to do with the prejudice against the operation. He appends some interesting notes from the pen of a daughter of the late Dr. Rigby, from which it appears that a single puncture, instead of multiple punctures, was formerly deemed sufficient as a protective against variola. Dr. Rigby was a friend of Jenner, and worked with him. He also maintained that a single puncture was less likely to be attended with inflammation than would be multiple punctures.

SCARLET FEVER IN LONDON.—The scarlet fever which has been epidemic in London for some time shows no sign of abatement, though it is, fortunately, of a mild type.

The Medical Record

Original Articles.

HOW CAN THE MEDICAL PROFESSION AID THE BOARD OF HEALTH?[1]

BY JOSEPH D. BRYANT, M.D.,

HEALTH COMMISSIONER, NEW YORK.

MR. PRESIDENT AND FELLOWS OF THE ACADEMY:

A short time ago the presiding officer of this Academy secured from the reader a promise to present a paper at this meeting of the Academy bearing on the relations that should exist between the Health Department and the medical profession of this city. This request was made during a conference that was being held by Dr. Jacobi and myself as the Medical Commissioner of the Health Department, relative to the feasibility of the appointment of a medical board to the Willard Parker Hospital for Contagious Diseases, and of the willingness of Dr. Jacobi to accept a position on the board. It was stated, as a reason for this step, that the profession of medicine of this city was somewhat ill informed of the previous and present organization of the board, of its aims, and of the methods employed for the accomplishment of its purposes. I comply with this request most willingly, since it must appear to everyone that the medical profession of this city and the Health Department should act in complete harmony with each other on all matters relating to the public health. It cannot be denied, I think, that they are at present, and have been for some time, greater strangers to each other than the immediate associations of their presence and purposes warrant. The reasons for this, both presumptive and real, should form no part of this evening's discussion.

The present and the future only should concern us. Each should labor with common purposes—the prolongation of human life and the alleviation and prevention of human suffering. Indeed, it will be strange if intelligent and humane individuals, who are prompted by these common purposes, be not able to act harmoniously in the interest of common good. The Health Department deals with measures for the prevention of disease rather than with those of a curative nature. The members of the medical profession necessarily devote themselves more to the cure of disease and to the alleviation of the physical distress incident to it than to the prevention of disease. Boards of health have the power to enact laws and the sanction and support of laws that are established for the purpose of affording them effectiveness in the performance of their duties; laws which, if properly interpreted and firmly yet honestly enforced, can but beget a public sense of confidence and security in those who administer them. On the other hand, if an unwise or illogical use be made of a power to create or to enforce laws, public distrust, followed by public indignation and public revolt, soon reduces the administrative fabric to ruins, and often there lie buried beneath them, for a time, the health, the enterprise, and the prosperity of the people. The members of the medical profession are not controlled in their action so much by written as by unwritten laws, yet they are none the less amenable for the violation of lawful precepts, since confusion, distrust, and dishonor follow each other in rapid succession as the results of the violations of accepted principles. It follows, therefore, logically, legally, and properly, that the preventive means of the Health Department, supported by a just interpretation and enforcement of its sanitary laws, should command the respect, confidence, and co-operation of the medical profession, actuated by its laws, in order that the consummation of the common purposes of each may be productive of the greatest good. With the view of paving the way to this co-operation, I have selected as a suitable title for the paper of the evening, "How can the Medical Profession Aid the Board of Health?" Before proceeding to state *how* this can be done, it is but proper that the profession should be informed (1) of the previous organization of the department; (2) of the present organization; (3) of its purposes and the means of attaining them. From January 2, 1884, until about August 1, 1887, the organization was as follows:

First, Secretary's Office.

Second, Attorney and Counsel's Office.

Third, The Sanitary Bureau. This was subdivided into seven different divisions, to wit:

First Division: Charged with all sanitary matters, particularly in connection with tenement and lodging houses, their occupants, and generally as to public buildings.

Second Division: Charged with all matters requiring the services of an expert in connection with the adulteration of food and drink, and with offensive trades.

Third Division: Charged with all matters endangering health, life, or limb upon the streets and sidewalks, and the enforcement of ordinances relating to nuisances exposed to public view, as well as special in-door inspections of all tenement and lodging houses.

Fourth Division: Charged with all matters relating to the detection and prevention of contagion; vaccination and disinfection.

Fifth Division: Charged with all matters relating to the care and maintenance of hospital buildings, treatment of patients therein, and their transportation to and from the same.

Sixth Division: Charged with all matters relating to the execution of the laws relating to plumbing and ventilation, construction of new buildings, and special inspections.

Seventh Division: Charged with all matters relating to the registration of births, marriages, and deaths, and the issuing of burial and transit permits.

This plan of organization was of a semi-military character, and it was intended that the subordinates of the Board should move, in the performance of their duties, with something of the precision that characterizes the systematic acts of bodies of men trained for the accomplishment of a common purpose. Suffice it to say, however, that from a practical stand-point this method of organization was soon found by the present commission to be more ornamental than useful, more confusing than assuring, and, in fact, more circumlocutory than direct in its advances.

With somewhat rapid strides changes were instituted by the present commission, which, it is believed, has greatly increased the scope and efficiency of the work of the department. Not a little of the success that has thus far attended these changes depends on the renewed *esprit de corps* of those who are intrusted with the execution of the duties of the department.

[1] Read before the New York Academy of Medicine, November 3, 1887.

The following is the plan of organization at the present time :

(1) Secretary's Office ; (2) Attorney's Office ; (3) Sanitary Inspection ; (4) Contagious Diseases ; (5) Food and Drink Adulteration, and Food Inspection ; (6) Plumbing and Ventilation and Construction of New Buildings ; (7) Vital Statistics.

The first decided change that was made was the transfer of Dr. Roger A. Tracy to the position of Registrar of Vital Statistics. Dr. Tracy is believed to be particularly well fitted for the duties of this position, by reason of his sound education and the natural inclination he has for this kind of work.

At the same time the first and the third divisions were consolidated and placed in charge of the inspector who formerly had control of the third division only.

The great majority of the sanitary inspections and the search for nuisances are done by lay sanitary inspectors and police sanitary inspectors. Of the former there are forty-two ; of the latter, fifteen. For the purposes of police sanitary inspection the city is divided into forty-two separate districts, on a basis of equality of work and individual responsibility. A sanitary policeman is placed in charge of each of these districts. His duties consist in making a thorough inspection of the tenement-houses of his district, making complaints for the abolition of all nuisances, and attending to such other duties as may be required of him by the department. The lay sanitary inspectors are men who are selected on account of the education, intelligence, or experience they possess. Their duties are, to attend to the citizens' complaints, and to inspection-problems that are too difficult for the police sanitary inspectors. They are also to correct special nuisances that occur, in connection with many other buildings than tenement-houses, in their districts.

There are fifteen lay inspectoral districts in the city, which are so arranged as to meet the demands of time and sanitary requirement in the performance of the duties of each. At the present time the medical sanitary inspectors are detailed to the department of contagious diseases, and devote their time exclusively to examining and combating all contagious diseases that come to the notice of the department. They are directed to visit the location of a contagious disease at once, to examine the premises closely for the detection of any defects that may be associated with the development or propagation of contagious disease, make complaints against defects, and afterward see that a strict compliance with the orders of the board regarding them be enforced. They are likewise told to offer disinfectants, instruct in their use, and observe if they be properly employed. They are directed to enjoin suitable isolation and observe that it be maintained.

They warn the people of the existence of contagious disease in their dwellings, and advise them of the necessity of avoiding exposure to it. Finally, they trace the disease to its source, and, by doing so, they not infrequently uncover a rich mine of unsuspected contagion. When it is impossible to provide and maintain proper isolation or proper medical treatment, the affected ones are requested to go to the hospital of the department. If the diseased persons be in contact with business-proceedings, as a place for the active sale of commodites of any kind, it is required that the business-place be closed or that the patients be removed. The medical inspectors engaged in this duty are emphatically told that they must co-operate with the physicians in charge of the patients, in every instance, and to do so with the strictest professional courtesy to the hospital.

It is intended to cause a careful scrutiny to be made, at no distant date, of phthisis and other diseases of a similar nature. The long experience of the medical sanitary inspectors as nuisance-searchers and examiners of citizens' complaints, taken in connection with the fact of their being educated physicians, makes their work in these matters of great importance and causes it to be skilfully performed. The placing of the medical sanitary inspectors at legitimate medical work, instead of retaining them at duties that are not infrequently inconsistent with all the instincts of educated gentlemen, can but increase their *morale* and efficiency. And it affords them the opportunity to investigate disease, the consideration of which has formed the basis of their life-study. The salaries of these and other positions have been graded in a manner that will offer a financial encouragement for a performance of duty that will be measured entirely by their own worthiness. The division of contagious diseases includes the bureau of vaccination and the consideration of contagious diseases in animals. This division has two special diagnosticians of contagious diseases, and no patient is removed to a hospital of the department unless the diagnosis have been made, or confirmed, by one or both of these gentlemen. And finally, to throw every possible safeguard around suspected cases, the Health Commissioners have appointed Dr. Prudden, of the College of Physicians and Surgeons, and Dr. Biggs, of Bellevue Medical College, as pathologists of the Health Department and of the hospitals under its charge. And it is but proper to say, at this time, that these gentlemen have proven the value of their services and the wisdom of the selection already in diagnosticating cholera by developing its cultures from the contents of the intestine of a suspected case at quarantine. The department has ample and comfortable means for the conveyance of patients to its hospitals, for all ordinary emergencies.

The hospital-accommodations are likewise adequate for the present need. Believing that the extent and character of the hospital-accommodations of the department are not appreciated by the majority of the members of the medical profession of this city, I will take the liberty of encroaching on your time sufficiently to briefly outline them. At the foot of East Sixteenth Street there are located the Willard Parker Hospital, for the treatment of contagious diseases, and also the reception-hospital for the patients who are under observation, and for the temporary abode of those to be removed to North Brothers' Island. The Willard Parker Hospital is an imposing brick structure, with good appointments, and with ample accommodations for seventy-five or one hundred patients. It is now occupied for the treatment of diphtheria and scarlatina only. And when you are told that the general care of the patients is supervised, at present, by a medical board composed of Drs. E. G. Janeway, A. Jacobi, C. R. Agnew, Stephen Smith, D. M. Stimson, G. F. Shrady, and J. D. O'Dwyer, it requires no further words on the part of anyone to indicate to all concerned that no pains is being spared to make the hospital worthy of the fullest confidence. The house-physician, too, is experienced and faithful to every trust. The reception hospital is likewise under the supervision of this medical board. Ordinarily it is occupied by two or three patients, and is sufficiently spacious for usual requirements. However, if the resources of this building were to be tested by the occurrence of an epidemic of other than the eruptive fevers, it would be found sadly inadequate in respect to capacity, safety, and comfort. Still, it is confidently believed by the Commissioners of the Health Department that their recommendations in such an emergency would be supported by the public authorities with a degree of earnestness that would render these defects generally remediable. On North Brothers' Island there is a suitable building for the treatment of small-pox, and also five completed pavilions for other contagious diseases. The pavilions will accommodate twenty-five to thirty patients each, with safety and comfort. There is also a considerable area of unoccupied surface upon which temporary structures could be erected if need be. The capacity for cooking is ample, and the utensils for eating abundant ; the stock of clean clothes is liberal, and the preparations for disinfection

are not contracted. It is now contemplated to provide disinfecting apparatus of sufficient capacity to enable the department to disinfect all textile fabrics that may have become associated with any form of contagious disease. This course is deemed to be absolutely essential to a successful struggle with this class of diseases, especially in the populous portions of a tenement-house community. Steps have been taken lately to render the reporting of contagious diseases and births, by the members of the profession, of as little expense as possible to them. However, candor compels us to state at this time that this course was taken, not only to relieve the members of a tax which appeared to be an unwise if not an unjust one, but also to disarm criticism on the part of those against whom the department may take action in the future for failing to comply with some of the legal requirements connected with contagious diseases.

As has been said already, in speaking of the transfer of the medical sanitary inspectors, great attention is being given to contagious diseases by the department at the present time. It is believed that, with a prompt reporting of contagious disease by the medical profession, combined with a cheerful and earnest co-operation with the board, that the contagious diseases of this city can be substantially abolished.

While the number of deaths from diphtheria per annum in this city is startling, yet the common occurrence of the funerals of the innocent victims of this disease has so familiarized the people with the grim spectre, that a mental estimate of the size of the coffin, attended by a casual remark of the death of a child, constitute the greatest part of the public sentiment that is excited by the funeral cortége. But if only one case of cholera were to happen within the city limits, gratuitous advice, gratuitous animadversion, and contumely would be heaped indiscriminately on the blameless and the guilty. It would be said that the commercial interests of the country, the business prosperity of the city, and every other interest dear to man, were imperilled! And all of this would be true, and on account of one case of cholera.

Still, there is scarcely a pronounced recognition from like sources, of an annual childhood death-rate from preventable diseases that eclipses any epidemic of cholera from which this city will ever suffer. The existence of cholera interferes with business interests, threatens the prosperity and lives of adults, imperils the selfish rather than the sentimental interests of men. When I inform you that it is estimated that at least fifteen to twenty-five per cent. of the cases of contagious diseases in this city are not reported, you will then see the great odds against which the Health Department must contend if it fight the existence of contagious diseases successfully. And I ask you, my medical friends and Fellows of the Academy, who is to blame for the influence of this proportion of the disparity of the conflict? It is estimated, also, that twenty-five to thirty per cent. of births remain unreported.

The permanent vaccinating corps comprises eight physicians. A few other physicians are appointed temporarily for this purpose, from time to time, as circumstances require. Vaccination is not enforced in any instance; yet, under some circumstances, it has been deemed advisable to use threats, and even a more active semblance of authority than these, to cause its acceptance, especially when great exposure has taken place in populous neighborhoods.

The Health Department can exercise as strict supervision of the food and drink commodities as the limited help for the duty will admit. A practical chemist is now in charge of this branch of the service.

The construction of tenement-houses as regards light, ventilation, and plumbing come within the jurisdiction of this department; and the prepared plans of construction of these habitations are submitted to the department for approval or disapproval. Any detection of a violation of the requirements of the law on the part of the architect or the owner results in the immediate correction of the construction, or in the arrest and punishment of the guilty parties. For the purpose of detecting illegal acts in connection with construction, the board employs a number of sanitary engineers, who are appointed for this purpose by reason of their special fitness for this line of duty. The premises are visited frequently by them, the approved plan of construction is compared with the plan in use, and whenever the latter differs from the former a halt is ordered and a strict compliance with the approved plan is then enforced. I could entertain you for some time with narrations of the shrewd, and often humorous, efforts that are made by the agents of builders to circumvent the requirements of the board. Not infrequently the misguided plumber will apparently ventilate the waste-pipes through the roof, by fastening to the roof directly an upright piece of pipe, which stands erect in the formal manner of a ventilated waste-pipe, but in reality is connected with nothing below the roof, except, perhaps, with the unsophisticated imagination of a newly appointed inspector. The Bureau of Vital Statistics is familiar to you all, for obvious reasons. In this division many preventive and precautionary measures against disease have been instituted, among which may be mentioned the requirement of an immediate and permanent enclosure of the body of a person dead of contagious disease within a tight casket. So much, in brief, can be said of the practical working of the Health Department from a medical stand-point alone. There is much more than this, but it must remain unrecited, both from want of time to express it and from the unimportance of its bearings upon the direct interests of the medical profession.

How the medical profession can aid the Board of Health.—The profession can aid the Board of Health in a most signal manner:

1. By reporting to the department at once all varieties of nuisances of which the members may become cognizant, that are recognized to be dangerous to life or detrimental to health.

2. By reporting all forms of contagious diseases at once, to enable the Health Department to apply quickly all possible means to prevent their spread. By doing this many valuable lives can be saved in ordinary times, and the occurrence of epidemics may be prevented.

3. By enjoining strict isolation of the patients and thorough antiseptic measures in contagious diseases.

4. By reporting to the board at once, for removal to the hospital, all cases of contagious diseases in which isolation cannot be practised or where adequate treatment cannot be provided.

5. By visiting the Willard Parker and other hospitals of the department at reasonable hours, to be able to inform the unfortunate sick of the admirable accommodaions provided by the city for their relief and comfort.

6. By discouraging the visits of the sick of contagious diseases to the dispensaries of the city. This act alone exposes to disease a large number of innocent persons, and is not a wise act for those already afflicted.

7. By co-operating with the medical inspectors of the board in every consistent manner, in the fight against contagious diseases.

8. By reporting to the board all food and drink adulterations that may come to notice.

9. By reporting all diseased or decayed food-substances to the board that may be known to the profession.

10. By giving attention to the subjects of plumbing, light, and ventilation in human habitations, and reporting to the board any violations of the law in respect to them.

11. By giving attention to plumbing construction, especially to be able to detect for yourselves and to inform your patients of the escape of deleterious gases into living and sleeping rooms.

12. By reporting births promptly, that the records of the department may show a correct annual birth-rate; also, to enable the department to locate those who may require vaccination.

13. By the appointment of a conference committee from your numbers, at once, of not more than five (5) members, which committee shall confer with the Health Department on all matters of health relating to the general public, when requested.

In making this statement, the Commissioners of Health feel that it is but proper that two organizations having the influence for good and the strength to enforce healthy doctrines, together with common personal interests in the public welfare, that are possessed by both the medical profession and the Health Department, should work harmoniously and actively together in the common cause —the present and prospective healthfulness of this great city.

LAPAROTOMY COMPLICATED BY TRUE HEMORRHAGIC DIATHESIS—PROFUSE PRIMARY AND SECONDARY HEMORRHAGE—TRANSFUSION—RECOVERY.

By CHARLES CARROLL LEE, M.D.,

PROFESSOR OF GYNECOLOGY IN THE NEW YORK POST-GRADUATE SCHOOL, AND SURGEON TO THE NEW YORK STATE WOMAN'S HOSPITAL, ETC.

I HAVE long ceased to report ordinary cases of laparotomy, as teaching nothing to improve our art; but when remarkable or unusual complications occur, I think the case should be recorded as a guide for future practice. With that object, and to illustrate the excellent results we sometimes obtain by the simplest means, I report the following case: A primipara, twenty-six years of age, consulted me, six months ago, with lacerations of the cervix and perineum. The left ovary and tube were prolapsed, swollen, and tender, and there was much uterine catarrh. These symptoms were greatly aggravated after menstruation, leaving no doubt of the existence of ovaritis and salpingitis on that side. The history indicated a severe instrumental labor, but no trace of subsequent peritonitis. The uterus was movable, and, after a short preparatory treatment, I closed the cervical and perineal tear. By this it was hoped that the pelvic condition would be so improved that the ovarian complication might gradually subside, but the patient was warned of the uncertainty of this. Unusual vascularity of the parts was noticed at this sitting; but as the sutures were securely adjusted, no apprehension was felt.

Within a few hours, however, secondary hemorrhage occurred from the perineum; and although this was never alarming in quantity, it was impossible for two or three days to arrest the flow. The patient was twice lifted from bed upon an operating-table, wheeled into a good light, and the parts minutely inspected. The hemorrhage was a general oozing, with no sign of the blood coming from a single vessel; and as the sutures had been very carefully placed, the wound was not reopened; a vulvar tampon was applied, and under this pressure the flow gradually ceased and the wound healed by granulation.

In six weeks the patient left my wards in the Woman's Hospital, where the operation had been done, and returned to her home in Maine. During the ensuing summer her family physician carried out the after-treatment suggested; but, in spite of this, no benefit accrued, and in September she returned to the Woman's Hospital with more acute ovarian pain and prolapse than before. Her suffering was constant and severe; the left ovary was larger, more tender than before, and adherent behind the cervix; the tube also was more distended, and the same conditions were beginning on the opposite side.

Rest in bed, with the hot vaginal douche, counter-irritation with iodine, and support by the boro-glyceride tampon were actively and thoroughly employed, but without result; and as the patient was clamorous for relief, she was told that only removal of the uterine appendages offered any certain prospect of cure. To this, after full consideration of its possible danger, both she and her husband assented, and on October 14th the operation was performed, before a number of spectators. On incising the abdominal wall more persistent bleeding was caused than I have ever encountered. Two or three small arteries spurted high above the surface, and from every point where the recti muscles were touched by the knife a steady stream of blood oozed. The linea alba was easily found, and only nicked here and there, and separated with the scalpel-handle and the fingers. On lifting the peritoneum with the thumb and finger, and then in smaller section with forceps, it was found very thick and vascular, with the intestine closely adherent to it at several points. With some difficulty a free space was found, and it was divided with scissors, in an irregular line, between the adherent loops. Copious bleeding here also occurred all along the cut edges. The tubes and ovaries were quickly found, isolated from their few adhesions, brought successively into the abdominal opening, ligated, and removed in the usual way. The utmost gentleness was used in separating the adhesions, no strain was put upon the broad ligaments, and the ligatures were tied with especial care. The right ovary (which was least affected) and all of both tubes were removed, as the patient desired the operation, if done at all, to be as radical as possible. Not a drop escaped above the ligatures, but on dropping back the last stump the pelvis was found half full of blood. This was thought to have come from the peritoneal and abdominal wounds, although flat sponges had been kept under these; it was carefully sponged out; but as it steadily reaccumulated, the abdominal wound was enlarged, the intestines crowded back, and with a good light the lower pelvis was carefully inspected.

The blood was now seen to ooze from the entire surface of the broad ligament, both above and below it, and from the walls of the pelvis. This was chiefly on the left side. Both pedicles were quite dry. Prolonged pressure with sponges seemed to stop the bleeding completely; a supplementary ligature was thrown around the base of the left pedicle as an additional security; a glass drainage-tube was inserted into the posterior cul-de-sac, and the abdominal wound was closed.

The patient had probably lost a pint of blood—possibly a little more—but her pulse was good, there was no special shock, and she reacted as usual. For four hours all went well, and there was no failure or other alteration of pulse; at the end of this time she vomited profusely, and immediately began to show signs of collapse. These were soon very serious and the drainage-tube was full of blood; the house-surgeon, confident that internal hemorrhage was occurring, sent at once for my assistant, Dr. Hanks, who was nearer to the hospital than I. Giving a little chloroform instead of ether, he reopened the abdominal wound and found the pelvis quite full of blood. This was rapidly sponged out, and with an excellent light the viscera were all minutely examined. Even now it was quite impossible to find the main source of bleeding. The entire under surface of the broad ligaments and the base of the pelvis steadily oozed, and here and there more vascular points emitted a steady stream; the pedicle ligatures were unaltered and the pedicles still dry. As before, the hemorrhage seemed chiefly on the left side. Additional catgut ligatures were applied to the chief bleeding points, torsion to others, the drainage-tube was replaced, and the abdominal wound closed with stout catgut. The blood removed from the pelvis had been collected in a basin, and was found to measure twenty-six ounces. The patient reacted slowly, and was excessively feeble; stimulating enemata were given, heat applied to the extremities, and the head was kept low. Three hours after this I saw her, with the house-surgeon, and at once de-

cided to perform transfusion, as she was still quite blanched and her pulse almost imperceptible. But as there was much jactitation, a preliminary hour was devoted to giving a hypodermic injection of morphia, and additional stimulants. At the end of this time, Dr. Outerbridge, the house-surgeon, made the first transfusion, which, it was agreed, should be with ten ounces of salted water, two and a half per cent. strong and 100° F. in temperature ; after the lapse of three hours this was to be repeated, if the first injection acted well.

This was accurately carried out ; and, although there was much difficulty in finding the median basilic vein, and our transfusion apparatus, when tested, was found defective—not an uncommon trait of elaborate apparatus of any kind—Dr. Outerbridge at once substituted a device of his own, which perfectly succeeded.

This was simply a tin funnel, none of glass being attainable, to which was firmly attached a piece of fine rubber tubing, ending in a large, blunt, exploring needle. By this means, and with the aid of a nurse alone, the injection was as easily managed as by any more scientific contrivance, and the admission of fluid into the vein was readily controlled.

No mishap occurred in its use. The effect on the patient was immediate and most gratifying ; but, as the amount injected was thought insufficient to produce a durable result, it was exactly repeated at the end of three hours. From this time the patient improved decidedly and steadily.

No trace of collapse recurred, the lips gradually recovered their natural color and the pulse an excellent volume, and these conditions were uninterruptedly maintained. The drainage-tube was regularly siphoned out every three hours ; for the first twenty-four hours about one teaspoonful of blood was obtained each time, but its color became steadily darker, and at no time indicated the occurrence of fresh hemorrhage. On the second day it became gradually more serous, and on the third ceased entirely. On the fourth it was removed, and a piece of fine rubber tubing substituted ; around this the opening, which still passed to the bottom of the pelvis, rapidly contracted.

For fear of fresh vomiting, and its injurious effect upon the pelvis, nothing was allowed to be given by the mouth until the fourth day—not even a drop of water—and the patient was sustained by enemata of beef-juice and brandy, with enough opium to quiet local and general irritation. When unusually thirsty, the mouth was simply rinsed with very hot water. The enemata were given every four or six hours. The pulse and temperature averaged about one hundred each during the whole of the first week, falling gradually to the normal standard on the sixth day. There was little or no peritonitis, the abdominal surface remaining flat and even.

On the eighth day the temperature unexpectedly ran up to 102° F., and the pulse to 120 ; the latter also lost its volume, and I feared the development of septicæmia. On carefully examining the abdominal wound, which, having been closed with catgut sutures, had not been disturbed, I found a mural abscess had occurred just above the site of the drainage-tube. This contained nearly an ounce of pus ; on evacuating it the pulse and temperature rapidly regained their former condition.

At this date—two weeks after the operation—the patient is entirely convalescent ; and it gives me pleasure to state that she owes her recovery and her life, first, to the prompt decision of Dr. Hanks, in reopening the abdomen ; and, secondly, to the intelligent skill and care with which, under circumstances that would have deterred many from attempting it, Dr. Outerbridge performed the transfusion.

The Emperor of Brazil has diabetes in its advanced stage.

SOME THOUGHTS ON THE ETIOLOGY OF SQUINT.

By SWAN M. BURNETT, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE UNIVERSITY OF GEORGETOWN ; OPHTHALMIC SURGEON TO THE GARFIELD HOSPITAL, AND DIRECTOR OF THE OPHTHALMIC AND AURAL CLINIC AT THE CENTRAL DISPENSARY, WASHINGTON, D. C.

When Donders pointed out, twenty-five years ago, for the first time, the fact that the eyes which squinted were almost without exception ametropic, and established the relation between convergence and accommodation, the etiology of strabismus was satisfactorily established in the minds of the majority of the profession, and remained almost unanimously so up to within a very few years.

Schweigger was the first observer of prominence to declare that this explanation did not explain all the facts in the case, and the publication of his monograph, in 1881,[1] marks the period of a reopening of the question ; and new evidence is now being furnished from all sides, and the discussions *pro* and *con* have of late been quite lively.

The present state of the controversy is well known to all specialists who keep *au courant* with the literature of ophthalmology, and it is unnecessary to refer to special persons or papers ; but for the benefit of the non-specialist it may be stated that for the production of squint several conditions are now assigned as essential by many different observers.

Among the first of the facts brought to light by the close examination of the eyes of those who squint was the difference in the visual power of the two eyes. The eye which habitually squinted was nearly always found to be defective in sight. When the squint was alternating—that is, when it affected first one eye and then the other—the vision was nearly always the same in each. From this fact was deduced the principle of *amblyopia ex anopsia*, where it was thought that the persistent exclusion of one eye from participation in vision was in time followed by a diminished visual power.

The examination of a large number of strabismics, however, has failed to show the constancy of association of ametropia with strabismus, and the value of ametropia as a factor is still further lessened by the fact that but a limited number of ametropic eyes squint, and some of the eyes which do squint are emmetropic. The logical inference, therefore, is that ametropia is not the sole cause of strabismus.

The next step was to look to the external ocular muscles themselves for a cause of the defect. It was thought by some that when one eye was not able, from amblyopia, to take part in vision, there was no incentive to hold the visual axes of the two eyes in such a position as would allow the images to fall on corresponding retinal points. While one eye, therefore, was fixed on the object, the other (amblyopic) eye was allowed to assume its normal position of rest, which might be inward or outward, or in a corresponding position to the other. It is, of course, assumed here that the amblyopia is antecedent to and, in a measure, a cause of the squint, and a correction of the strabismus cannot bring about an amelioration of vision, as is contended for by the advocates of *amblyopia ex anopsia*.

The whole question of converging squint was made the subject of full and free discussion at the last meeting of the British Medical Association,[2] and a perusal of the papers read and the comments thereon reveals a most unsatisfactory condition of the "squint" question. Almost every man had an opinion which differed by a shade from everyone else, and a student seeking exact knowledge on the subject would find himself in a whirl of conflicting views, from which it would be impossible to extract anything that was positive or assuring. The only impression that would likely be left on his mind

[1] Klinische Untersuchengen über das Schielen, by Prof. Dr. C. Schweigger. Berlin, 1881. August Herschwald. Pp. 152.
[2] British Medical Journal, September 24, 1887.

would be that there were more causes than one operating to bring about the condition of strabismus, and that further facts and observations on several different points were necessary before we could have clear views on the subject. At least such is my own present opinion on the question, and it is to contribute my modest quota of facts that I have written this paper.

In looking over the statistics of eye diseases observed by me at the Central Dispensary, I have been struck by the fact that the negro is afflicted with strabismus convergens to a very much less extent than his white brother. In a total of 3,740 patients there were 1,314 white and 2,426 colored. And of these there were 44 cases of strabismus convergens in the white and 7 among the colored. That is to say, there are about twelve times as many cases, proportionately, in the white as in the colored race.

It has seemed to me that this difference is something more than a mere coincidence, and a proper explanation of it would help us on toward a clearer understanding of the cause of squint. We are, unfortunately, not in a position to know with certainty the frequency of ametropia in the negro as compared with the white. In a clinical service which brings together only the very poor, who seldom or never use their eyes for accurate work of any kind, our statistics can hardly be considered as representing the true average condition. It is pretty certain, however, that myopia is much less frequent among the negroes, though there can be no question that the influence of education is beginning to be sensibly felt by them in that particular. I see now a considerable number of myopic negroes. The figures collected at my clinic show, among 1,314 whites, 30 myopes; among the 2,426 negroes, 9 myopes.

It is commonly supposed, on the other hand, that hypermetropia is more wide-spread among the less cultivated races. I find among the 1,314 whites 31 hypermetropes, and among the 2,426 negroes 27 hypermetropes. It will be seen from a study of the above figures that while there is, roughly, seven times as much myopia among the whites, there is still two and a half times as much hypermetropia. It is not a fair inference from these figures, however, that the white has more hypermetropia, for very few of the negroes suffering from hypermetropia would be likely to present themselves for examination on that account, their distant vision being quite sufficient for their uses, and there being no demand for any close work for the eyes. It is very important, however, for a proper settlement of this question, to know exactly the extent to which the negro suffers from hypermetropia. An examination of an equal and rather large number of the two races would be necessary, and it is a task which I have set for myself in the near future, should someone else not undertake it. Among the children of the public schools of this district, however, whom I have examined as private patients, I do not find any excess of hypermetropia among the negroes.

But granting that hypermetropia is equal among the whites and negroes, the enormous difference in the frequency of convergent strabismus still remains, which must be accounted for on some other basis.

Looked at broadly, the main difference in the use of the eyes in the two races, as found in this country, is the more *strongly fixed habit of convergence in the white.* The full force of this observation will become apparent when we remember that in the white race for generations the position of convergence has been the rule during a greater part of the waking hours, not alone in the student and man of letters, but in the mechanic and shopkeeper, and in all the occupations except that of the mere laborer. Up to within a few years the negro, with a few exceptions, was only a laborer, and the position of convergence was infrequently required of him, and only for a short time.

The internal recti muscles would, therefore, from greater use, become more strongly developed, and we should expect, *à priori*, that the position of convergence would be the position of rest, so called, as is contended for by Stilling.[1] It should be stated, however, that this statement of Stilling has been controverted by Gardiner.[2] Yet it must be acknowledged that the views of Stilling are philosophical, and the proof against them should be overwhelming before they are given up. We know that there is in convergent strabismus an increase of the power of convergence, due to a greater strength of the interni over the externi, not only relatively, but, so to speak, positively; that is to say, there is a power of turning the eye inward greater than in the normal condition. In only a limited number of cases are the externi positively weak. That in permanent squint there is a sort of contractured condition of the interni will, I believe, be admitted by all, and this condition is the legitimate result of the greater power and activity of those muscles.

It is not, of course, contended that there are not other causes operative in the production of the strabismic condition. I think it may be declared, without fear of successful contradiction, that no one of the various causes assigned can of itself bring about the condition of concomitant squint; but I think that, of them all, the habit of convergence is certainly one of the most powerful, and that the other conditions, hypermetropia, uniocular amblyopia, etc., are much less effective when it is not present. And whether this view is accepted or not, the main fact on which it is based—the less frequency of internal squint in the negro—remains, and must be accounted for in the final summing up of the evidence as to the etiology of squint.

A CLINICAL STUDY OF ERYSIPELAS IN INFANTS.[3]

By I. E. ATKINSON, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND OF CLINICAL DERMATOLOGY, IN THE UNIVERSITY OF MARYLAND.

Erysipelas has always been a source of disagreement among writers. By some it has been regarded as a non-specific inflammatory process arising from a number of different etiological influences;[4] by others, as resulting from one or another of a number of specific principles, now from the contagion of pre-existing erysipelas, now from that of puerperal fever, or, again, from the toxic effects of traumatic or surgical sepsis. Finally, there have been those who have considered it an affection comparable to the acute specific fevers, always developing from a definite morbific principle. To-day it is hardly worth while to discuss the question of its non-specific origin. The line of inquiry is between a complex of symptoms resulting from one or other of a number of pathogenic specific influences, which forms the pathological whole which we call erysipelas, and a disease arising from a fixed definite principle, in the absence of which characteristic erysipelatous inflammation cannot occur. These questions cannot be properly considered without due observation from both histological and pathological and clinical stand-points. There can hardly be any doubt that modern bacteriological research has practically determined that erysipelas depends upon the vital activity of minute organisms. It is far from being determined, however, whether the disease is produced by a single specific microbe, or by more than one, which, unlike in specific nature, call forth similar pathological results. Not to delay with earlier observations on the bacteriological origin of erysipelas, let us consider briefly the work of Fehleisen,[5] by which he claims to have discovered an organism, the erysipelas coccus, or streptococcus erysipelatis, the sole cause of true erysipelas.

---

[5] Der Aetiologie der Erysipelas. Berlin, 1883. Deutsche Med. Woch., 1882, vol. viii., p. 553.

This author asserts that the erysipelas coccus is distinguished from that of wound pus, pyæmia, and certain forms of abscess, through its behavior in cultivation. This microbe he found only in lymph channels, thus opposing the views of Lukmosky, Billroth, Ehrlich, and others, and immobile, though Hueter reported it actively mobile. It is identical with the coccus described by Koch. He was able to successfully inoculate rabbits and human beings with his cultures, and always produced a non-suppurative erysipelatous inflammation. Fehleisen claimed, therefore, to have established the streptococcus erysipelatis as the sole cause of erysipelas, excluding all erysipelas-like inflammations in which suppuration occurred, as not being truly erysipelatous, and in being without this peculiar streptococcus. Recent researches, however, throw considerable doubt upon the correctness of his observations and conclusions. Hajed,[1] for example, pursuing the same culture experiments as Fehleisen, sought to determine whether the streptococcus of erysipelas offered characteristics whereby it could be differentiated from the streptococcus pyogenes, one of the micro-organisms of pus and of phlegmonous inflammation. Not to delay over the very interesting details of his experiments, let it suffice to say that neither in their behavior under cultivation, nor under inoculation, did they present absolute differences. In their pathological histology, however, Hajed found notable points of dissimilarity. That is to say, while after erysipelas the cocci are to be found very sparsely, and almost exclusively, in lymph channels, rarely in the tissues, while cell-infiltration is abundant, in phlegmonous inflammation after the streptococcus pyogenes, while the lymph channels indeed are first invaded, we find the cocci vastly more numerous. The lymph-vessels are filled with them. The cocci are also abundant in the tissues. They seem to outnumber the tissue and inflammation products. He concludes that Fehleisen incorrectly limits true erysipelas in excluding all suppurative processes from it, as such may arise under accidental conditions, and that although the inflammation following streptococcus pyogenes is more constantly and intensely accompanied by œdema, that following streptococcus erysipelatis cannot be said to be quite free from it.

Eiselsberg[2] was quite unable to discover any difference between the two cocci, whether in cultivation, inoculation, or in microscopic structure. Bionti,[3] by cultures of streptococcus from phlegmonous abscesses, induced typical erysipelas in animals. Günther's observations did not enable him to decide as to the identity of the streptococcus found in phlegmonous suppuration with Fehleisin's erysipelas coccus. The whole question, therefore, is far from being settled. Under any circumstances, however, the clinician will not consent to accept as definitive any conception of erysipelas that restricts it to a migrating inflammation, never accompanied by œdema nor by suppuration.

It may be, indeed, that he will be compelled to recognize erysipelas, in a rigid sense, as a non-suppurative specific inflammation originating in a single specific organism, in the course of which atypical suppurative changes must be attributed to the accidental presence of one of the pus micro-organisms. Important as such conclusions would be in an etiological relation, they would not banish the difficulties of clinical diagnosis; for at the bedside one observes the simple non-suppurative form of erysipelas result from exposure to the phlegmonous variety, and *vice versâ*, and it becomes at once evident that the presence or absence of suppuration or of œdema can never be made the test of erysipelatous inflammation, nor determine the clinical diagnosis. For the present, then, one must be content with the general recognition that erysipelas is an infectious disease, owing its specificity to minute organisms, probably streptococci.

Erysipelas of infants can only be said to assume peculiar features when it affects those less than one year of age. The excessive fatality of the affection at this period of life cannot be ascribed exclusively to the blood-poisoning almost invariably associated with the typical form of erysipelas neonatorum, beginning at or near the navel during the first few days of extra-uterine life, for it is almost equally frequent in erysipelas, having apparently no immediate connection with disorder arising from infection through this channel. After the first month the mortality from the disease rapidly diminishes until the end of the first year of life, when it comes to have a course not essentially differing from that in older persons. When death does not result from pyæmic infection, with inflammation of internal organs and suppuration after a more or less rapid course, the infant may succumb to exhaustion from the persistence of erysipelatous inflammation in its tendency to wander over the general surface, a tendency especially observed at this period of life, and according to which the process may endure for weeks, leaving no portion of the integument at one time or another uninvolved. A third tendency, which, however, is not often observed, but which can hardly be said to occur in erysipelas, excepting as affecting new-born and nursing infants, is toward the development of a peculiar solid œdema or induration of the cutaneous and subcutaneous cellular tissues. Infantile erysipelas, then, is peculiar in its great fatality, its tendency to wander, and its occasional indurative infiltrations. Regarding its fatality there is so great unanimity that a few words here will suffice. Trousseau confessed that he had never seen an infant less than a month old recover, and quoted Dubois, Moreau, Moynier, Lebreton, and others to almost similar effect.[1] Of six cases less than six weeks old recorded by J. Lewis Smith,[2] all died. Occasional recoveries, even at the earliest age, have been observed, however. Elsässer[3] reported the recovery of a boy, fourteen days old when attacked. Of fourteen cases collected by Gob,[4] six recovered, but four of these were of vaccination erysipelas. One infant, with erysipelas beginning near the navel on the ninth day of life, finally recovered. Other recoveries under similar conditions have been recorded, but they only serve to accentuate the high rate of mortality of the disorder in tender infants.

Doubtless the most important influence in the high mortality of erysipelas in the new-born is its frequent dependence upon the poison of puerperal fever, for, beyond question, it is of most frequent occurrence in those exposed to this infection. This is shown by the reports of many writers. J. Lewis Smith[5] has recorded the experience of Dr. Colby, of New Bedford, Mass., in 1840. This gentleman, suffering from a sore finger, with suppurating axillary glands, derived from a necropsy, attended within a few weeks fifteen lying-in women. All the mothers died with symptoms of metro-peritonitis, and all the children had erysipelas and died within a week after their seizure. Confirmatory evidence is abundant. Nevertheless, this infection cannot be the only cause of the fatality of the disease, since newly born infants beyond the influence of puerperal affection are sometimes attacked with erysipelas, which exhibits the same severity. While erysipelas neonatorum is admitted to be most dangerous when beginning at or near the navel, it is hardly less so when beginning on the neck or elsewhere. Since, however, it is now almost universally admitted that erysipelas is always derived from some pre-existing contagion, specific exposure must be assumed in all cases. It is interesting, however, that in recognizing a puerperal and a non-puerperal origin in these cases one must admit that unlike special influences induce similar pathological results.

Whether in older persons the spread of the inflammation

be more controlled by the peculiar arrangement of Langer's cleavage lines of the skin, is difficult to say. The fact of less restraint upon the spread of erysipelas in children is well known. The following cases illustrate this tendency, and at the same time the more rare cutaneous induration of which mention has been made. The first case was distinctly not due to puerperal contagion, the second case occurred during the puerperium.

Case I.—Female, seven weeks old; mother's convalescence normal. Though at first the child did not thrive, in consequence of deficient supply of mother's milk, recently she had begun to grow vigorously after the addition of cow's milk to her diet. She had been restless for a day or two, when, on the evening of November 20th a small red spot was observed on the neck, just behind the right ear. The surface was somewhat elevated, and under it a small enlarged gland could be felt.

November 21st.—The spot had spread to the cheek and involved the ear. It extended into the scalp, and on the neck reached to the clavicle. There was high febrile excitement. The inflamed area was very painful, and the baby would cry out frequently with sudden severe pain. Somnolence was marked. There was but slight infiltration of the erysipelatous area, which was bright red, but without vesicles. The bowels and kidneys were sufficiently active; wheaten flour was dusted over the inflamed surface. One grain of quinine sulphate three times daily, and two drops of the tincture of the chloride of iron every third hour were prescribed.

November 22d.—Child drowsy, crying out with distress at intervals. The eruption had crept to left side of the face and neck. Pulse rapid and fever decided. The tincture of iron was increased to four drops every third hour. Twenty drops of brandy were ordered to be given every fourth hour.

November 23d.—Slight disturbance of respiration; slight cough and wheezy breathing. Stupor continued.

November 24th.—The eruption had extended over entire face to half of forehead. On the back it had extended nearly to the hip on the right side. Both ears were reddened and swollen. Any movement excited intense pain. The bowels had been moved three times.

November 25th.—The eruption had almost disappeared from the head, but covered entire back to the hips, sharply margined inferiorly.

November 26th.—Both arms were invaded; the perineum and vulva also, but the child seemed better.

November 27th.—Was quite restless last evening, but slept well later. Is taking one-third drop of tincture of opium every fourth hour. The child is better. The eruption is now very faint upon the body, but is brilliant upon the thighs and both arms almost to the wrist.

November 28th.—Eruption nearly gone from body and legs and arms. Forearms swollen and reddened beyond wrists. Child very fretful. Skin much darkened from pigmentation following the hyperæmia. Over belly, back, and thighs are scattered several areas, irregular in shape and somewhat elevated, sharply circumscribed and brilliantly red; areas of erysipelatous inflammation returning upon parts that have already been affected. The temperature has shown itself to depend for its variations upon the varying extent of surface involved, lighting up with renewed vigor upon every marked extension of eruption.

Until December 4th the fever and eruption continued with varying intensity, the latter never quite disappearing from the extremities, but leaving the trunk, neck, and head almost free, except for occasional eruptions of circumscribed extent and transitory duration, though erysipelatous in character. Upon this date the temperature rose rapidly to 104° F., and upon inspection the hands and feet were found to be much reddened, swollen, and shining. There was some cough, but no signs of consolidation of lung. While emaciated the infant did not seem especially depressed.

On the 5th the legs had become very œdematous and indurated, imparting to the hand a sensation as of very tough, almost hardened, clay or mortar. The arms were also very œdematous, and there was some œdema of the face. With difficulty a sufficient amount of urine was collected for chemical examination. It was found to be quite free from albumen. Desquamation was free, except in swollen parts. From this time there was no renewal of the erysipelatous inflammation, and the œdema slowly subsided, retaining for some time the mortar-like solidity, and pitting only very slightly to ordinary pressure. While it lasted, the skin was not tender and hot as during the acute inflammation, yet it did not feel unduly cold. The skin of the indurated area was darkened from pigmentation, and was not livid from intra-vascular changes.

By December 11th fever had subsided and convalescence was established. The treatment throughout consisted in slight variations of that adopted at the outset—the administration of iron, quinine, and small quantities of opium. Small doses of brandy were administered as required. The local treatment consisted in the application of dry wheaten flour copiously. Convalescence was established on the twenty-first day of the disease, which had been marked by great and irregular variations both of pulse and temperature; the latter varying from 99.2° F. to 104.4° F., the former from 150 to 192 to the minute. A striking feature throughout the period of erysipelas of the trunk was the high rate of the respiration, ranging from 48 to 72. It was easily demonstrated that this was not due to pulmonary complications, but resulted from the unconscious effort of the child to avoid the painful movement of the chest and belly-wall consequent upon deep inspiration.

No lesion could be detected at the point where erysipelas originated, and no erysipelas nor septic disease was known to be in the vicinity. The next case that I shall present differed from this in occurring during the puerperium, in more intense induration of the tissues, and in its fatal termination.

Case II.—Mrs. B—— was safely delivered of her second child, a girl, on March 14th. She convalesced without untoward symptoms. The child thrived until the 23d, when she was observed to be restless and to cry out vehemently whenever disturbed. I saw her the next day, and upon stripping her found the right knee-joint enlarged and globular, but not elastic. No other symptoms were evident. The cord had come away naturally, and the navel presented a healthy appearance. There was no redness of the skin. The infant nursed well and voided its urine and fæces naturally. A belladonna ointment was applied to the knee.

March 25th.—The knee was still more swollen, but the child was more comfortable. Its axillary temperature at 10 o'clock A.M. was 101° F.

March 26th.—An erysipelatous redness had now appeared at the right labium majus, extending without a sharp line of demarcation over a limited area of the right abdomen. The navel was covered with a thin, brownish crust, but was not swollen or reddened. The head and upper extremities were flecked with reddish spots, without infiltration or tenderness, fading on pressure. One drop of the tincture of the chloride of iron was now given every fourth hour. By 8 o'clock P.M. both labia were intensely red, indurated, and swollen. The redness extended over the belly and buttocks, but without œdema or induration. Pulse, 162; respiration, 100; temperature, 103° F.

March 27th.—The infant was drowsy. The labia, buttocks, and belly were brawny and red. At 8.45 A.M. the temperature was 101.2° F.; pulse, 162; respiration, 100. Bowels had been moved three times. There was no cough. Examination revealed no pulmonary abnormality. Inflammation had extended well down both lower extremities. The red maculations continued to come and go upon trunk, head, and upper extremities.

Condition of knee-joint unchanged. Evening temperature, 102.2° F.; pulse, 168; respiration, 70. Belly less red and inflammation not extending upward. During the next twenty-four hours the condition remained unchanged. No active extension of inflammation occurred. None of the erythematous transitory maculations became frankly erysipelatous.

On the morning of March 30th there was apparently great improvement, the temperature falling to 99.2° F., and the redness not extending, but at 8 P.M. the temperature had risen to 102.4° F.

March 31st.—Without further extension of inflammation the belly, hips, buttocks, and lower extremities had become densely indurated. The integument of these parts was of a dusky red color; it was intensely infiltrated, and of a board-like hardness; it did not pit to pressure, but resisted the fingers, as would a nearly hardened clay model. During the next two days there were several marked remissions and exacerbations of temperature.

April 2d.—The temperature at 10 A.M. was 99.2° F., at 6 P.M. it was 102.4° F. During the day the erysipelatous redness extended over the back and shoulders, but without œdema and induration. The thighs, lower portion of the belly, the buttocks, and external genitals were more solidly indurated than ever. It should be noted that the integument of the belly, after having become much less infiltrated and softer than at first, again acquired a still greater induration.

The child's condition had become decidedly less favorable. A number of greenish, slimy evacuations from the bowels were had during the day, and she refused the breast. She remained quiet, occasionally whimpering, but was readily composed by two one-quarter-drop doses of laudanum, given with an interval of four hours. Quinine in one-grain doses had been administered every sixth hour during the day, but was rejected by the stomach and its use was abandoned. Brandy, gtt. xx., every third hour.

April 3d.—The child was very much worse. The morning temperature was 99.1° F., the pulse 138, respiration 84. During the past two days emaciation had been rapid and evident. There was no extension of the eruption, but the thighs, belly, and buttocks, though paler, were of a board-like hardness. Desquamation was noticeable over the spots which had been erythematous early in the disease. The swollen knee-joint remained unchanged. The legs and feet were dusky and swollen, but not indurated. The affected area, which had been until now dressed with dry wheaten flour, was pencilled with a solution of silver nitrate—grains xxv. to the fluidounce of distilled water.

April 4th.—The lower extremities were mottled and cyanotic. Thighs, belly, and buttocks retained their board-like hardness; they were livid and presented numerous ecchymoses. The external genitals were indurated as before, but livid, and apparently about to become gangrenous. The board-like hardness merged imperceptibly into the œdema of the neighboring parts. The parts implicated were not, and had not been at any time, colder than the rest of the surface, but gave the impression of solidity and absolute immobility upon subjacent structures. Death occurred quietly at 10.30 o'clock A.M., after a slight convulsion. The kidneys were active throughout.

The source of this erysipelas could not be ascertained. The mother had no puerperal inflammation. There had been no infectious disorder in the house. I had seen no erysipelatous nor septic disorder for many weeks. The nurse denied any dangerous exposure, but was reticent, and opportunity of ascertaining her antecedents was not afforded. No necropsy was permitted.

The first point of interest in the preceding case is the fact that the erysipelas was preceded for two days by pronounced enlargement of the right knee-joint, with febrile movement. This would indicate that, contrary to what is the usual experience, the noxious principle acted from the circulation and not by the gradual extension of a local infection. The fugitive erythema appearing concurrently with the erysipelas would bear out this theory of mortification, since similar eruptions are well-known concomitants of septic blood-infection. That the primary inflammation was not centred around the umbilicus does not indicate that the poisonous virus gained admission by another channel. Erysipelas neonatorum by no means always begins just at the navel, even excluding cases of vaccination erysipelas. It is well known that erysipelas neonatorum frequently first appears in the pubic region and about the external genitals, especially in girls, and attention has long since been directed to its development at points more or less distant from its probable point of entrance, and more particularly to its appearance near, rather than at, the navel.[1] This course has been observed by a number of writers. Elsässer[2] has recorded a case closely simulating my own observation. A boy, fourteen days old, had fever. *After four days* erysipelas appeared upon his thigh. After two more days the knee and calf were invaded, and the skin became hard as in scleroma. This child finally recovered.

The peculiar induration of the erysipelatous tissues, although uncommon, has been observed by so many writers that its presence can hardly be regarded as accidental. Earlier writers undoubtedly confounded erysipelas with ordinary scleroma infantile; and one (Hemmer) probably after the observation of cases like the one just described, considered scleroma to be a sequel of erysipelas neonatorum.[3] This induration of the connective tissue with and after erysipelas has been described by Trousseau, Hervieux, Elsässer, Bierbaum,[4] Hellft,[5] and others. Older writers describe the association of infantile erysipelas with induration of the skin and subcutaneous connective tissue with more care than more recent observers. This is partly due, probably, to their confounding scleroma with erysipelas; but a number of cases are upon record where undoubted erysipelas was accompanied or succeeded by the morbid condition now under consideration. Trousseau has seen this connective tissue induration invade not only the parts that had been attacked by erysipelas, but even those that had remained free from the inflammation. He relates the following case (given in brief): The mother died on the fourth day with puerperal fever. On the sixth day the infant was seized with erysipelas of the prepuce, the navel freely suppurating. The erysipelas attacked successively the inferior extremities, the trunk, the arms, but stopped at the neck. Fever and general distress were marked. On the seventh day the redness seemed to disappear from the affected parts, but during the day the infant became hard. The induration involved the entire body, including the face. The limbs were cold, and gave the same sensation as a frozen corpse. Death occurred eight days after the beginning of the attack. This case could have well been a scleroma following erysipelas. Hervieux[6] declared that the only differences between the symptoms of erysipelas of adults and erysipelas neonatorum were found in the latter when complicated with scleroma, when "the tumefaction is accompanied by an uncommon, at times almost stony hardness." In such cases he noted an almost complete absence of fever. He regarded such cases as the concurrence of erysipelas and scleroma. Elsässer relates three cases of erysipelas neonatorum in which the parts affected became almost as hard as stone. This author, however, does not make clear the difference between "acute sclerosis of the newborn" and "erysipelas neonatorum" complicated by scleroma. Hellft[7] details the histories of two infants in whom the erysipelatous character of the inflammation

was clearly expressed, and in whom the induration was unquestionably dependent upon it. He notes the frequent confounding of this condition with sclerosis or scleroma, and indicates the points of differentiation. His description of the course of the disorder is very accurate, and, so far from confounding it with scleroma, he carefully indicates the diagnostic differentiation. Scleroma, he declares, occurs only during the first days of life. (Of two hundred and forty cases reported by Billard, not one was more than eight days old.) From the first, the skin is pale white or yellowish. If at the beginning the skin is red, this redness speedily fades. Coldness and want of sensibility are characteristic of the scleromatous skin. A febrile condition is not observed. Profound depression of the vital powers is manifest from the first, and infants attacked are usually meagre and badly nourished.

It is noteworthy that the induration of the cellular tissue succeeds rather than accompanies the erysipelatous inflammation. This was the case in both of my patients, and was observed in the recorded instances to which I have had access. That the induration is due to an intense œdema, with cellular exudation, would appear probable, and that it is an extreme degree of the œdema that so often accompanies erysipelatous inflammation is altogether likely. In my first case the induration was solid, but more or less plastic, while in my second case it was of a board-like hardness. In neither case was there suppuration, but in the second case the brownish-red, brawny condition of the affected parts indicated that local gangrene was only evaded by the death of the patient. In fact, suppuration and gangrene are exceedingly rare in primary erysipelas. They occasionally occur, however; and in erysipelas neonatorum, suppurative pleuritis, peritonitis, etc., may be observed.

It is claimed in this article that "erysipelas" represents a pathological process that may find its exciting cause in irritation proceeding from morbific principles of different nature which produce in the organism similar results; that it represents a symptom-complex rather than an essential disease, and that erysipelas should be regarded as an inflammatory process of symptomatic character, just as we know that suppurative inflammation may be excited not by a single, but by several micro-organisms. The following two cases still further support this opinion:

Case III.—I was called to see, at the Home of the Friendless, a male infant, aged seven months, on July 4th. It was stout, and had always been healthy until it took measles early in June. It had an ordinary attack and convalesced fairly well. Some enlargement of the cervical and submaxillary glands remained. It had, when I first saw it, an attack of cholera infantum. This was controlled after two days.

On July 7th it had moderate fever, and its neck became markedly swollen. The outlines of the glands became lost in the dense hardness of the whole posterior surface of the neck and occipital region, and under the jaws. This was accompanied by redness and great œdema of the face and posterior and vertical portion of the scalp. The swelling was especially pronounced on the left side of the head, and gave the child a most grotesque appearance. The face was pallid, the expression anxious and distressed. The neck and scalp very much indurated. The head was as if set upon the shoulders, and immobile. A diffuse cellulitis, such as has been called by older writers erysipelas fixum, was diagnosticated. As the child had still diarrhœa, a mixture for this disorder was continued, and twenty drops of gin given every fourth hour. As milk had not agreed, beef-tea was given as an exclusive diet, for the present. The neck and scalp were poulticed.

By the 9th suppuration had occurred in the right suboccipital region. Much thick yellow pus was let out by free incision.

On the 10th the general condition was improved. With the dressing-forceps shreds of connective tissue and glandular substance were removed, and the probe could be swept around for a considerable distance toward the median line. The induration of the other parts continued, but there was much less œdema of the face and no tendency toward extension of the inflammation.

11th, suppuration over left occipital region. Lanced. Swelling of neck and scalp much less, but hardness persisted.

13th, two small pockets of pus over occiput were lanced. A number of small accumulations of pus were now freely opened daily until the 17th, when the general condition was very much improved. The openings generally communicated, and were syringed out with a carbolized solution (1 : 20). Improvement thenceforth was constant.

Case IV.—On July 14th my attention was drawn to an infant, six months of age, in the next crib to Case III. It had also recovered from measles, and although puny, had not required treatment. For two days the nurse had observed enlargement of the submaxillary glands of the left side.

On the 15th there was a slight erythematous redness over an enlarged gland below the angle of the jaw.

On the 17th there was an erysipelatous eruption extending over the side of the face and neck, and nearly reaching the scalp on the forehead. It was sharply circumscribed and slightly œdematous. The pulse was 180; the temperature 102.3° F. Bowels regular. Respiration easy. Flour was dusted over the eruption, and two drops of the tincture of the chloride of iron given every fourth hour. This marked the height of the disorder, which thenceforth steadily declined, the temperature becoming normal on the 20th. The œdema and erythema rapidly disappeared. Desquamation appeared duly, and the case terminated favorably as an ordinary attack of facial erysipelas. It is, of course, possible that these two children may have been infected independently of each other. So many instances of the appearance of erysipelatous inflammation under almost identical conditions are upon record, however, that a community of origin between such inflammations is exceedingly probable, especially in view of the experimental observations quoted in the early portion of this paper.

It may be said, in conclusion, that while the writer cannot assent to the assertion of even such distinguished authority as Jonathan Hutchinson,[1] that erysipelas is a non-specific disease and of spontaneous origin, he is by no means of the opinion that it is specific in the sense that it is due to a single specific organism, as are smallpox, scarlatina, etc. He agrees with a number of writers who think that it may be an expression of one or more of a number of specific causes; that it should be regarded as a symptomatic inflammation, in which its exciting micro-organisms, themselves differing in nature, react upon the economy in a more or less similar manner, and of the activity of which it may be only one of several phenomena; that while experimental observation may establish the identity of the streptococcus erysipelatis of Fehleisen, as a micro-organism capable of exciting erysipelas in man and other mammals, by inoculation, neither experimental research nor clinical observation will establish it as the sole cause of even the restricted form of erysipelatous inflammation to which its discoverer would apply the term erysipelas. Finally, it may be said that no conditions are more favorable to the establishment of these opinions than the observation of erysipelas of new-born and nursing infants, which in other respects differs from that of older persons in its greater tendency to migration, to a protracted course, and to a fatal termination, and, last of all, to the occasional development of an œdematous induration of the affected connective tissue to some extent resembling scleroma neonatorum.

Clinical Department.

GONORRHŒA IN YOUNG CHILDREN.

Dr. J. S. Prettyman, Jr., of Milford, Del., writes: "On August 25th, D. L——, aged nine years, was sent to me by a physician from a neighboring town to be operated upon for phimosis. Upon examination I discovered that he was suffering from acute urethritis with balanitis, and refrained from operating. He admitted having several times in the previous three weeks attempted sexual intercourse with a colored girl, seventeen years of age. Two days afterward an older brother, aged eleven, came to me with the same disease and acknowledged infection from the same source. They were both treated for gonorrhœa and are now entirely well.

"Ten days ago I visited Miss ——, aged nine, the youngest member of a family of excellent social position, and found her with a severe urethritis and vaginitis. She had already been treated three weeks by external applications to the vulva, her physician thinking she had a cutaneous disease. Not wishing to humiliate the girl I refrained from interrogating her in regard to the source of infection, but diagnosed gonorrhœa and put her under treatment. At present she micturates without pain and the discharge has entirely ceased. In these cases the physicians had failed to diagnose the disease because they did not expect to see gonorrhœa in children so young."

FRAGILITY OF THE UMBILICAL CORD.

J. Henry Fruitnight, M.D., of this city, writes: "An extract from a discussion which took place at a meeting of the Société de Médecine Légale of Paris upon the subject of the fragility of the umbilical cord appeared in a recent number of The Record (Vol. xxxii., No. 14).

"From this discussion the inference is drawn that in the opinion of some of the participants the occurrence of a separation of the integral portions of the funis is somewhat doubtful. Very little bearing upon this subject is to be found in works treating of obstetrics. However, in the last edition of Cazeaux and Tarnier's 'Theory and Practice of Obstetrics' the affirmative of the proposition is maintained, and the condition is designated as a weakness of the umbilical cord. These authors ascribe this weakness as due either to a deficient development of the cord itself, or to a particular mode of distribution of the umbilical vessels, or to an oblique attachment to the placenta.

"The same writers also discuss at some length rupture of the umbilical cord *ante partum*, assigning as causes some diseased condition of the vascular coats, a particular arrangement of the vessels or a shortness of the funis, either *per se* or as a consequence of repeated turns of the cord around the various portions of the fœtus. In connection with this phase of the subject they cite many cases and authors.

"As bearing upon this subject, it will be interesting to submit a brief history of an opposite case which occurred in my practice. Early one morning about six years ago I was urgently summoned to visit a woman, a multipara, in childbirth, who at the time was under the charge of a midwife. When I arrived at the bedside of the patient, I found upon investigation that the child had been born, the funis having been deligated *secundum artem*. But to the consternation of those present, when the midwife attempted to deliver the placenta the umbilical cord was severed from that organ, probably in consequence of her vigorous efforts at traction, for nothing abnormal could be detected about the funis. This detached segment of the funis measured about fourteen inches in length, and the line of fracture of its torn extremity was oblique from above downward. The placenta with the remainder of the cord attached was still *in utero*. Upon a vaginal examination I discovered that the uterus was contracting and that the os had closed considerably, as nearly an hour had already elapsed since the birth of the child. After considerable difficulty and gradual manual dilatation of the os, accompanied by abdominal compression and traction upon the placental mass, the afterbirth with the attached portion of the funis, measuring about two and one-half inches, was expelled.

"Of course, the separation of the funis from the placenta after the birth of the child does not, in itself, affect the safety of either the mother or the child. Separation or rupture *ante partum* obviously has a very serious import as regards the life of the child, and, in a minor degree, the safety of the mother is also imperilled. Nevertheless, as a guide to the position and attachment and easy delivery of the placenta, it is highly desirable that the integrity of the cord should be preserved. As intimated by the authors already quoted, there is a slight possibility that in a case of this nature the uterus may be dragged down. Still, if the physical characters of the placenta be recollected and abdominal palpation be practised the experienced accoucheur will not be apt to have this happen in his hands. My case, added to the others alluded to in the above-mentioned discussion, would seem to sustain the argument that the umbilical cord *is* frangible."

FLUID EXTRACT OF PICHI IN VESICAL CATARRH.

Dr. H. S. Delamere, of Lubec, Me., referring to the use of pichi in the treatment of catarrh of the bladder, as reported by Dr. G. T. Comstock, relates the following case:

"A. B——, aged twenty-eight, had been suffering for two years from vesical catarrh. He had had gonorrhœa, but a No. 21 (French) bougie passed without difficulty, causing, however, considerable vesical tenesmus. When I was called to see him he was passing urine every hour during the day and four or five times during the night. The urine was alkaline, ropy, ammoniacal, and the microscope revealed pus. I gave the usual remedies prescribed in country practice, such as buchu, uva ursi, etc., but without benefit. I then resorted to washing out the bladder by means of the double-channel catheter, with the effect of relieving my patient slightly. The least exposure, however, aggravated all the symptoms and caused as much suffering as ever. After about a year and a half of constant treatment, with no other result than to keep the disease at bay, I received a sample bottle of fluid extract of pichi, which I tried. After the patient had taken it a few days he expressed himself as feeling better. He was now getting up twice during the night. But the sample was gone, and I was obliged to wait until I could get a fresh supply. In the meantime the patient grew worse; had to get up three or four times during the night. As soon as the drug arrived I commenced giving him twenty drops four times a day, which dose I increased to thirty drops. In a few weeks my patient was so much better that I abandoned washing out the bladder, and today he is at work. The urine is clear, free from mucus and pus, and has no ammoniacal odor. He sleeps well, and does not have to get up more than once during the night. Notwithstanding he has suffered recently from a severe cold, the bladder-trouble has not returned. The man's general appearance is healthy, appetite good, and he seems well."

A CASE OF SCARLATINA WITH COMPLICATIONS.

Dr. W. U. Taylor, of Movers, N. Y., writes: "The case reported by Dr. Miller in The Medical Record of October 8th, recalls a somewhat similar case that occurred in the practice of the late Dr. C. H. Bidwell, of this town. The child, about five years of age, had a mild attack of scarlet fever, for which he had little or no

treatment. During the second week, while convalescent, dark spots appeared upon the arms, extending within twenty-four hours to the trunk and legs. When I saw the child—forty-eight hours after the appearance of the purpura—the trunk and extremities were covered with irregularly shaped spots looking like bruises. The oldest and most superficial were turning yellow; the deeper and later were still purple, some almost black. The great toe of the right foot was gangrenous, as was the left foot and leg half-way to the knee—the skin being black, with vesicles filled with bloody serum scattered over it. As the case progressed, acute nephritis, albuminuria, suppression of urine, and general dropsy appeared. The left tonsil suppurated, and was incised; convulsions with left hemiplegia appeared, followed by suppurative otitis of left ear. Two weeks afterward, after having been given up by everyone, the boy began to improve. A line of demarcation formed about six inches below the knee, the right toe sloughed off, and in a tew days we amputated the leg. The case made a good recovery. The paralysis disappeared within a year, and now—two years later—the boy runs about either on his knees or with one crutch. Have not tested his hearing, but understand he is somewhat deaf in the left ear. Here was a series of complications! Scarlatina, purpura hemorrhagica, nephritis, suppurative tonsillitis and otitis, dropsy, convulsion, paralysis, gangrene, amputation, and *recovery*. The latter would hardly be called a complication. Possibly it would be considered accidental."

NUTMEG POISONING.

Dr. W. T. Dodge, of Marlette, Mich., reports the following cases: "In June, 1886, I was called to see two children, a girl about four years of age, and a boy about eight, who had been left at a farm-house alone all day and were discovered acting strangely on the return of the family in the evening. An investigation discovered pieces of nutmegs about the house, and the little girl stated that she had eaten one, but had vomited, and that the boy had eaten two. He soon becoming stupid, his parents became alarmed and sent for me. I found him in a semi-comatose condition, and immediately administered an emetic and diffusible stimulants. He vomited freely, but the coma increased until it was soon impossible to give him anything by the mouth. Hypodermic injections of brandy, ammonia, and small doses of sulph. of atropia were given, and artificial respirations were continued all night, but the little fellow did not rally, and died at an early hour the following morning. There was complete suppression of urine. The little girl became partially unconscious about two hours after the boy was taken, but could be at all times easily aroused and was all right in the morning. It will be seen the symptoms were similar to opium poisoning, but there was no opium in the house, and there appeared to be no doubt that the death of one child and the symptoms shown by the other were caused by eating the nutmegs. I think both children would have died had not the little girl vomited soon after eating."

LIGATURE OF THE CLITORIS IN A YOUNG CHILD.

Dr. George F. Wilson, Assistant Surgeon, United States Army, of Fort Shaw, Mon. Ter., sends the following communication: "On the morning of August 29, 1887, I was asked to go a distance of about twelve miles from this post to see a girl six years of age, who had been taken seriously ill on the previous evening. As the messenger spoke English very imperfectly, I was unable to obtain a very satisfactory history of the case. He stated that the child had been put to bed at its usual time, in good health apparently, and that about ten o'clock she began to cry out with pain. The parents then examined the child to find the source of the trouble, and discovered that something was protruding from her vagina. On arriving at the house I asked to see the patient immediately, as the mental distress of the parents rendered their account still more bewildering. The patient, a thin and poorly-nourished girl, was lying on the bed, her clothes completely saturated with sweet oil, urine, and the water from many hop poultices, which latter had been constantly applied since the discovery of the trouble. Just above the meatus, and occupying the site of the clitoris, was a small, tense, œdematous swelling, about the size of a marble, and separated from the normal parts by a deep sulcus. As every attempt to examine the lump was met by struggles and screams on the part of the patient, and cries of despair from the parents, I was obliged to administer a small quantity of ether. When partially under the influence of the anæsthetic the child voided her urine, which operation caused the lump to move about as if lightly suspended, at the same time bringing into occasional view the orifice of the meatus, which was to no extent involved in the swelling. As soon as the patient became quiet I proceeded to examine the mass, and while rather at a loss to account for the trouble, I saw two small ends of thread projecting from the sulcus, anteriorly. Traction on each, separately, failed to loosen them, but I was then convinced that they must be the ends of an encircling ligature. Acting on this supposition I squeezed the tumor between thumb and fingers, which relieved much of the tension, so that the bottom of the sulcus became visible. A thread was discovered then and cut with scissors, after which gentle pressure with the fingers restored the parts almost to the normal, to the very great joy of both parents. As the only other member of the family is a child about three years of age, I presume the girl must have tied the string herself. The sex, extreme youth, and undeveloped condition of the parts are, to my mind, the unusual features of the case."

FRACTURE OF THE BASE OF THE SKULL—RECOVERY.

Dr. F. H. Jenks, of Aurora, Ill., reports the following case: "I was called to see T—— on the evening of May 21st. All that could be learned from the patient's friends was that he had jumped from a wagon in a runaway. There was a scalp wound in the left parietal region and a contusion in the left temporo-occipital region. Blood was oozing from both ears, from the nose, and mouth. There was œdema and ecchymosis of both eyelids; the epidermis was scraped from right cheek; the alveolar process of the superior maxillary bone on right side was fractured from the body, the fragment containing three teeth, and there was paralysis of the muscles of the face on both sides. About two days after the accident it was discovered that the external rectus muscle of the left eye was also paralyzed. The patient was delirious until about noon the next day, when he entered into a partial coma, which began to disappear in about four days. Consciousness was fully restored in about nine days after the accident. The highest temperature observed was 99.1° F. Treatment mainly ice to head and bromides. In twenty-four days the patient was walking around the house, suffering comparatively no discomfort except from paralysis of the extreme rectus of the eye and a queer feeling in the head. At this time the patient passed from my care, returning to his home in Pennsylvania. The case is of interest for two reasons: First, the paralysis indicated the locality of the fracture, and second, the amount of cerebral and meningeal injury was comparatively small. Had the injury to the brain been of any moment it must necessarily have proved fatal in spite of any treatment."

Progress of Medical Science.

The Use of Pilocarpine in the Treatment of Acute Affections of the Respiratory Organs.—Following the advice of leading French physicians, Dr. Wyss has lately frequently used pilocarpine in acute affections of the respiratory organs. In many cases speedy relief was observed. Dr. Wyss prefers the internal use of this drug, to which patients more readily submit than to subcutaneous injections. He prescribes: ℞. Hydrochlorate of pilocarpine, half a grain; distilled water, three ounces; to be divided into two or three equal parts by the graduation of the phial. Of this, one-half or one-third is to be taken directly after having retired to bed. The following cases will illustrate the action of this remedy (*Der Fortschritt*):

1. *Acute coryza*, in a young man aged twenty-one. Two days after attack, respiration through the mouth, violent frontal headaches, intense congestion, and tumefaction of the conjunctiva; pharyngeal dryness. One-sixth of a grain of hydrochlorate of pilocarpine at bedtime. Great relief since the first night. Recovery in three days.

2. *Acute laryngitis.*—Miss S——, aged twenty, a teacher of singing. Complete loss of voice; congestion of the whole interior of the larynx; grayish-yellow secretions covering the vocal cords. Pilocarpine, one-sixth of a grain, at bedtime. The voice considerably clearer since the morning following the first dose of pilocarpine. After eight days the voice was perfectly clear and normal, and the patient was able to resume her lessons.

3. *Acute pharyngo-laryngitis*, in a man aged forty-four. The patient had been suffering since three days, especially during the nights, from frequent attacks of suffocation in consequence of the intense œdematous swelling of the inter-arytenoid space. Complete loss of voice; moderate, thick, grumous, grayish expectoration. One-sixth of a grain of pilocarpine at bedtime. Voice restored on the morning following the first dose. The tumefaction of the inter-arytenoid mucous membrane had almost entirely disappeared; no more attacks of suffocation. The patient resumed his occupation as foreman in a large factory, continuing, however, the pilocarpine for a week.

4. *Acute laryngo-bronchitis.*—Patient, aged forty, in bed, suffering from violent dyspnœa and labored, loud respiration; the voice hoarse; the laryngeal mucous membrane, especially the vocal cords, intensely red. Temperature, 101.3° F. One-fourth of a grain of pilocarpine at night. This dose had very powerful effects: violent colics, cold perspirations, the feeling of sinking (the patient feared to die) during three hours, but on the following morning so manifest a relief and improvement that on the same day he was able to attend to his usual duties. From this time uninterrupted recovery.

5. *Bronchitic asthma and hypertrophic rhinitis*, in a lady aged thirty-two. The patient, for eight days, had been obliged to pass half the night sitting up with the windows opened. Pilocarpine, one-sixth of a grain, at bedtime. Since the first evening considerable relief, the patient being able to rest the whole night in bed and sleep quietly, undisturbed by any more attacks. Discontinued the pilocarpine after twelve days. This patient, who had been for nine years a great sufferer from asthmatic attacks, stated that no other remedy had ever given her such rapid and permanent relief. She has been free of attacks since she took the first dose of pilocarpine.

Urobilinuria.—Professor Hayem recently read an article giving the results of his researches on urobilinuria. He demonstrated how, by the aid of the spectroscope, urobiline may be recognized in the serum of the blood and in the urine. According to him, the excretion of an abnormal quantity of urobiline constitutes urobilinuria. This phenomenon may be transitory, or it may be intermittent, or it may present itself in a permanent manner. When the affection is slight, the color of the urine is scarcely altered, but when well marked, we have the hemaphetic urine of Gubler. Urobiline is found in the urine, either alone, or associated with a more or less considerable quantity of biliary pigments. It is frequently met with in intoxications, diseases of the liver, cerebral affections, and in certain chronic maladies. It is also frequently met with in the greater part of acute affections. Dr. Hayem does not believe that urobiline alone can produce jaundice. He had been able to establish, in all cases in which he observed urobilinuria, a venous stasis of the liver with slight catarrh of the biliary ducts, and with infiltration or fatty degeneration of the hepatic cells. According to Hayem the diseased liver, instead of secreting normal pigments, secretes urobiline, which, according to certain clinical facts, would pass directly from the biliary ducts into the blood. In conclusion, Dr. Hayem establishes the prognostic value of the symptom of urobilinuria as follows: When temporary it indicates temporary modifications of the hepatic circulation. When permanent, it indicates infiltration or fatty degeneration of the hepatic cells.—*The Journal of the American Medical Association*, *October* 8, 1887.

Fatal Paralysis Following Measles.—Although Landouzy, in his work on the Paralysis of Acute Diseases, asserts that, without being exceptional, paralyses are less frequent with measles than with variola, yet it may be questioned whether measles is not, rather more frequently than is generally supposed, the efficient cause of obscure nerve disease among children. Dr. Négrié, of Bordeaux, has observed a case of acute ascending paralysis consecutive to measles. The child was three years of age, and on the tenth day of full convalescence after measles considerable weakness was first discovered in the upper and lower limbs and in the muscles of the neck. Headache, pains in the limbs, and fever were other symptoms. The paralysis increased in degree, so that sitting was impossible. The knee jerks disappeared and the plantar reflexes appeared to be diminished. Before speaking, the child was noticed to make some jerky inspirations. Sensation and the sphincters were not affected. Paralysis of respiration seemed to be the principal cause of death, which took place five days after the onset of the paralytic symptoms.—*Journal de Médecine de Bordeaux.*

Reflex Neuroses from Constipation.—Besides disturbances of the circulation, and especially palpitation, irregularity of pulse, and vertigo, which may be attributed to excitation of the cardiac branches of the great sympathetic, Kisch believes that rebellious hemicrania often recognizes no other cause than constipation (*British Medical Journal*). Certain kinds of sciatic neuralgia, and lumbo-abdominal pains, or ovarian aches, and even neuralgiæ of the fifth pair, have been ascribed to habitual constipation. Although Kisch has collected forty-eight cases in which cessation of constipation was followed by relief from diverse and chronic neuralgiæ, we may well question whether intestinal sluggishness was the *causa causans* of the various neuralgiæ. The alteration of even one element cannot be effected without the production of more than one result.

The Spread of the Tubercle Bacillus by Flies.—The question of the spread of the tubercle bacillus by means of the common house fly is considered by Drs. Spillman and Haushalter. The authors state that they have seen flies enter the spittoons containing the sputum of phthisical patients. The flies were then caught and placed in a bell-jar. On the following day several of them were dead. Examination of the abdominal contents and the excrement of these flies showed the presence of many tubercle bacilli. The authors point out the wide dissemination of the disease which may take place in this way.—*La Semaine Médicale.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, November 12, 1887.

THE CAUSE AND TREATMENT OF WHOOPING-COUGH.

IN 1870 Letzreich claimed to have discovered the micro-organism of whooping-cough. A few years later Peshamer attributed the disease to a vegetable parasite which he found in rotten apples, and thought that whooping-cough was a mycosis of the respiratory tract. Rossbach, Birch, Hirschfeld, Deichler, and very recently Afanarsjen (*Allgem. medizin. Central-Zeitung*, No. 85), have described special organisms believed to be peculiar to pertussis. The results of all this work, excepting, perhaps, those of Afanarsjen, leave it still a matter of doubt as to what is the cause of whooping-cough.

The marked contagiousness of this disease and its peculiar course, however, have produced a very general belief that it is of parasitic origin, and remedies based upon this theory have been frequently brought forward of late years.

In 1874 Burchardt advised the use of inhalations of solutions of carbolic acid, 1 to 2 per 100. Peck, Davezac, Goldschmidt, and others, subsequently recommended the same agent given in the form of sprays or vapors, and it is the unanimous opinion that the course of the disease was shortened to three or four weeks. But Hagenbach claims that it is the watery vapor which does the good, and Professor Vogel, of Munich, has obtained no favorable results at all. Dr. Covy, and also Dr. Suckling, have given carbolic acid internally in doses of one-third of a minim. In twenty cases treated by Suckling the disease lasted only fifteen days. Illingworth asserts, however, that carbolic acid does not suffice in severe cases. Thymol has been substituted for carbolic acid with some success. Salicylic acid was first used by Otto, who gave daily inhalations of a two per cent. solution.

It has also been given internally at night in doses of ʒss. to ʒj., with the effect of checking the excesses of coughing and vomiting.

Dr. Paul Cheron, in *L'Union Médicale* of October 18th, gives a list of nine persons who have testified to the efficacy of quinine in whooping-cough. At the recent German Congress of Internal Medicine, Binz praised the drug in question, but insisted upon the importance of giving large doses. Kolover projects against the back of the throat the following solution: R. Quinine sulph., gr. xlv.; acid sulphuric, ♏xxx.; aquæ destill., ʒvj. M. This is repeated every two hours. He states that at the end of the first week the cough has disappeared entirely. Poskin gives from ten to thirty grains of the tannate of quinine every night. Binz and Hagenbach also recommend the tannate, but it is an expensive preparation in this country.

We have already described in these columns the method of treatment by inhalations of resorcin devised by Moncorvo, of Rio Janeiro. Dr. W. Hedger has confirmed the observations, but finds it difficult to carry out the treatment in young children.

Half a dozen writers have reported favorably upon the use of turpentine, either by inhalation or internally.

The peculiar mode of using sulphurous acid, as recommended by Mohn and Schonberg, and described in this journal a year ago, has been tried by Kaurin in nineteen cases, but the results were poor and quite unlike those claimed by Mohn. Others, however, speak favorably of inhalations of sulphurous acid, of course greatly diluted, and Bergeon claims that by rectal injections the disease is shortened.

Another of the modern methods of treating pertussis is by making applications to the nasal mucous membrane. This treatment is based on the theory that the disease is really due to an irritation in the posterior nasal fossæ and naso-pharynx, the cough being a reflex symptom.

Michael has followed out this mode of treatment most extensively. He makes applications of benzoin, quinine, or tannin to the supposed pathogenic localities. At the last Congress at Wiesbaden he reported the results in two hundred and fifty cases. Of these twenty-five per cent. were not improved, seven per cent. were cured in two or three days, twenty-three per cent. in less than twenty days. Dr. Bochem, of Bonn, and Drs. Moizard, Cartaz, Guerder, and Guy have all reported good results by this method. The powders employed have been composed of benzoin, quinine, bismuth, or boric acid and coffee.

Cocaine has been extensively tried in whooping-cough, it being both given internally and applied locally. It produces some relief of symptoms, but it is not free from danger, and it is by no means curative.

Among internal medicines nothing seems to have superseded belladonna and the bromides.

REPORTS ON THE ADULTERATION OF FOOD AND DRUGS.

THE Report of the State Board of Health of New York for the Year 1886 is at hand, and contains some interesting investigations regarding the adulteration of food and drugs. The question of adulteration with copper, of imported beans and peas, is taken up, and all the evidence regarding it is presented. It is shown that these vegetables contain from one-third to one-half a grain per pound of copper, equivalent to about four times that amount of sulphate of copper. It is the unanimous opinion of French experts that this amount is harmless, and the French government allows the sale of the vegetables so prepared, provided that the fact of the coloration by copper is stated on the labels.

Samples of spices, cream tartar, and saleratus were ex-

amined for the board by Mr. S. A. Lattimore. Among three hundred and seventy-six specimens he found that two hundred and fifty-five were adulterated. The samples of black pepper, cream tartar, and cinnamon were impure in more than half the cases.

It was also found that one-half of the forty samples of kerosene oil examined flashed at a lower temperature than 100° F.

Dr. Lewis Balch makes a report upon three hundred and six samples of drugs analyzed by him. Twenty-three per cent. of these were of inferior quality, and eighteen per cent. of fair quality.

Of fifty-eight samples of chloroform, twelve were of inferior quality, and of fifty-nine samples of ether twenty-five, or nearly one-half, were of inferior quality.

Professor G. C. Caldwell made an analysis of a very large number of samples of quinine pills. The results obtained by him are stated as follows :

1. The frequency with which quinine sulphate, sold by the druggists, contains a notable excess of foreign alkaloids.

2. The short weight of quinia in the citrate of iron and quinine as usually sold. While the United States Pharmacopœia requires that this preparation shall contain twelve per cent. of the alkaloid, not a single sample examined this year came up to this standard, while some fell seriously below it ; the poor quality of the quinine used in it is also noticeable.

3. The not infrequent occurrence of more or less short weight of quinine sulphate in the pills, as well as of a poor quality of the article used in their manufacture.

THE CANNON-BALL IN THERAPEUTICS.

It is a very self-evident proposition in physics that a cannon-ball, as ordinarily propelled, will, upon its abdominal impact, produce a movement of the bowels. Such a movement, however, is attended with the serious personal inconvenience of producing a large hole in an important portion of the economy. And it is not in this way that Dr. H. Sahli, of Bern, (*Correspondenz-Blatt für Schweizer Aerzte*) proposes to utilize the cannon-ball in therapeutics. He advises that it be simply rolled about upon the abdomen for five or ten minutes daily, in order to relieve habitual constipation. The weight of the ball should be from three to five pounds. In cold weather it can be covered with chamois, or kept warm by the stove. Better still, according to Dr. Sahli, is the plan of having the patient take it to bed with him at night, and thus letting the missile of war warm itself ingloriously in the arms of the victim of colprostasis. The best time to use the cannon-ball is in the morning, after waking. It is then to be made part of the morning toilet; the patient lying on his back in bed rolls his ferric bedfellow systematically over the abdomen. The direction is not of so much importance, as that of systematically treating every part of the abdominal wall. Abdominal massage is acknowledged to be a useful measure in torpidity of the bowels, and Dr. Sahli assures his readers that by his method he has been able to cure nearly all of his cases without the aid of medication. Of course, proper attention should be paid to diet and hygiene.

When universal peace comes, the orator can speak not only of turning swords into ploughshares, but also of cannon-balls into aperients ; while of Dr. Sahli it may be written : "Peace hath its victories, no less renowned than War."

IRON AND POTASH IN DIPHTHERIA.

Probably no remedy is more uniformly prescribed in diphtheria, in this region at least, than tincture of iron and chlorate of potash. What must be thought of therapeutic certainties, therefore, when gentlemen come forward and boldly assert that the remedy is useless and ought to become obsolete.

Thus Dr. Herbert L. Snow writes to the *British Medical Journal* that he much regrets to find "that the old-fashioned treatment of diphtheria by tincture of iron and chlorate of potash has not yet become obsolete. This mixture," he adds, "has no effect whatever upon the diphtheritic membrane, and cases thus treated are in all probability left to run their natural course, little assisted by the supposed remedy. On the other hand, if sulphurous acid be administered in full and frequent doses we at once see a rapid disappearance of the exudation, with corresponding improvement in the patient's general condition. In severe cases a drachm should be given (to an adult) every half-hour ; in ordinary ditto, every two hours ; and proportionately large doses to children. The only drawback is the choky sensation produced by the vapor, otherwise the mixture (with syrup and water) is rather pleasant in taste. It is thus necessary to prescribe a large quantity of syrup—two or three ounces in an eight-ounce mixture. For young children the dose must be given in milk. It is generally very advantageous to add chlorate of potash, in order to promote the healing of the ulcer ; probably also for other reasons. No spray or gargle is requisite, but the patient should be directed to gargle a little with the medicine each time this is swallowed—a task not always possible however."

There are somewhat over sixty different remedies recommended for diphtheria, among which chlorate of potash and tincture of iron have received perhaps the greatest number of endorsements, sulphur and its preparations coming next. The wish expressed that iron and potash may become obsolete, is equivalent to an admission that the only remedies of any use are simple cleansing applications and a sustaining and stimulating diet.

LIVER SURGERY—SUCCESSFUL CHOLECYSTENTEROSTOMY.

The result of the surgical operations upon the gall-bladder and the ducts of the liver have been by no means discouraging. Among thirty-three cases of cholecystotomy collected by Dr. Gaston (Wood's "Reference Handbook") there were nine deaths, or 27.27 per cent. Among the last twelve operations there was only one death. The incompleted operations have been more fatal, but their number is small. The more complicated operation of "cholecystenterostomy"—*i.e.*, of uniting the gall-bladder and intestine by a fistulous opening on account of closure of the common duct—has as yet been attempted but few times, and the best methods for its performance, as well as the nature of the results, are still undetermined. This operation, suggested by Nussbaum

in 1880, was first performed by Winiwarter a year later (*Prag. Medic. Wochensch.*, 1882, No. 21 u. 22). A number of experimental observations were subsequently made by Harley, Witzel (*Deut. Zeitsch. f. Chir.*, 21 Bd., S. 199, 1885), Golzi (*Centralbl. f. Chir.*, 1886, No. 24), and Gaston (*Brit. Med. Journal*, February 5, 1887). The latter author in particular devised an ingenious operation which goes by his name, but one which Kappeler considers too uncertain and dangerous to be applied to man.

Professor O. Kappeler has recently (*Correspondenzblatt f. Schweiz. Aerzte*) reported a case of permanent closure of the common bile-duct, with consequent icterus, in which he successfully united the gall-bladder to the intestine, and thus established a new path for the passage of the bile. The patient was a man fifty-five years of age, who suffered from obstructive jaundice, due, as the operation showed, to pressure on the ductus choledochus by a pancreatic tumor. The gall-bladder was greatly distended. The operation consisted of emptying the gall-bladder and stitching an opening in its walls directly to a corresponding slit in the duodenum. The operation is described as simple and safe. In any event, it was successful in Kappeler's hands. He terms it a "unilateral cholystenterosectomy."

News of the Week.

The Demand for a Three Years' Course of Lectures and medical study is becoming so great that it can soon no longer be ignored even by schools which are ambitious of the largest possible classes. Recently the Executive Committee of the Alumni Association of Jefferson College adopted the following resolution:

Whereas, It having come to the knowledge of this Executive Committee of the Alumni Association that four students have gone to the University of Pennsylvania to pursue their medical education, at the recommendation of the Alumni of this College, on the ground that Jefferson Medical College did not provide a three years' graded course, and did not furnish clinics or instruction on the special branches of medicine and surgery. Be it

Resolved, That the Executive Committee, having the best interest of our Alma Mater at heart, respectfully announce these facts to the Faculty, that they may take such action as they deem best to overcome this apparent growing dissatisfaction of our Alumni.

New York Skin and Cancer Hospital.—An examination of candidates for the position of House Physician of the New York Skin and Cancer Hospital will be held at 243 East Thirty-fourth Street on November 19, 1887, at 8 P.M. For information apply, before November 15th, to L. Duncan Bulkley, M.D., 4 East Thirty-seventh Street, New York.

Gleditschine, so called, will be duly investigated by a committee of experts.

A Liberal Endowment.—Professor Babes, of Buda-Pesth, has become ordinary professor of histology and bacteriology in the University of Bucharest. The offer made to him was munificent; he will receive an annual salary of 25,000 francs (£1,000), and a sum of 100,000 francs is placed at his disposal for the expenses of fitting up the histological and bacteriological institution; altogether, half a million francs will have been spent on this institution.

The Crown Prince's Case.—The manly letter of Mr. Lennox Browne to the London *Times* concerning Sir Morell Mackenzie and the Crown Prince's case is most creditable to the writer, especially in view of the fact that there has been reported to be some slight antagonism of late between the two laryngologists. The following paragraph will be read with interest. Mr. Browne writes: "Sir: It is earnestly to be hoped that you will not allow a long discussion to be conducted in your columns on the very false issues so unfairly raised by 'F.R.C.S.' as deductions from your admirable leader of yesterday. The question should in no sense be considered from a national point of view. The patient endurance and, indeed, the marked preponderance of favor which have been so long accorded to German views and to German practitioners resident in this country, are too striking to warrant any jealousy on the part of the German nation or of German physicians, that English medicine has at last had a chance of asserting its claim to at least an equality of cosmopolitan rights." The report that a new growth has appeared in the Crown Prince's throat has occasioned, justly, great consternation. The growth is below the vocal chords, and probably the operation of thyroidotomy will have to be performed.

Bequests to Hospitals.—By the will of the late Frederick H. Cossitt, a large numer of charitable institutions, among them St. Luke's, the Presbyterian, and the Woman's Hospitals, the House of Rest for Consumptives, and the Home for Incurables, have received legacies; the amount in most instances being $5,000.

The Death of Dr. William Seldon, an old and prominent physician, of Norfolk, Va., occurred on November 7th.

An Illustration of the Practical Usefulness of Bacteriology was furnished recently in this city. An Italian steamer arrived loaded with immigrants. There had been no cholera on board, but, as the vessel reached this port, a suspicious case of diarrhœa occurred in a child. The symptoms were not perfectly typical of cholera. Some of the dejections were taken, and sterilized tubes were inoculated and taken to the Carnegie Laboratory in this city. It would take four days to develop the cultures, and the question arose whether the steamer should be delayed for that period of time. It was finally decided to do so. The cultures developed in the way characteristic of Asiatic cholera, and the diagnosis was made. Subsequently other cases of cholera appeared and the culture-diagnosis was abundantly confirmed. But no more striking example of the utility of scientific studies could be furnished than the one referred to.

In Order to Give Sulphur so that it will be excreted by the lungs, Dr. Battesti prescribes the monosulphide according to the following formula: Monosulphide of sodium, 1 gramme; distilled water, 500 grammes. One

teaspoonful of this solution contains one centigramme of the monosulphide, and he gives one or two spoonfuls a day, according to the tolerance of the patient. This dose is equivalent to about one litre of *Eaux Bonnes* water. Calculations based on the chemical equivalents of monosulphide of sodium and of carbonic acid show that one-fourth of a litre of this gas is sufficient entirely to decompose one gramme of monosulphide. The patient, therefore, takes one teaspoonful of the sulphurous solution, and immediately afterward one tablespoonful of Rivière's potion or a glass of seltzer water. Rivière's potion is preferable, on account of its smaller volume. The dose is taken fasting, or four hours after a meal. Dr. Battesti has obtained the best results from this treatment.

The Recommendations of the State Board of Health of New York, in its last Annual Report, deserve attention from physicians. They are:

I. That its organic law be so amended as to authorize its executive officer, where an emergency arises and the local board of health of the town or village in which the emergency occurs has not organized and appointed a health officer, to appoint a physician as acting health officer at the expense of the town or village concerned, who shall, until such time as a board of health for said place has been organized, as provided for in chapter 270, Laws of 1885, have and exercise, under the direction of the Secretary of the State Board of Health, all the powers and duties of a board of health regularly appointed.

II. That the following requirements be embodied in a law as essentials to the sanitary welfare of the school-children of the State:

(*a.*) Building should rest on a good dry foundation, and be constructed to insure the comfort of children during inclement weather.

(*b.*) Class-rooms should be arranged so as to admit light from left side and back of pupils, and the area of windows should be one-fourth of floor-space.

(*c.*) Not less than 250 cubic feet of air space should be allowed per pupil, and provision for changing air should be made, so as to secure each pupil not less than thirty cubic feet of fresh air per minute.

(*d.*) The temperature of the school-rooms should in winter be maintained at a range not to exceed from sixty-eight degrees Fahrenheit to seventy degrees Fahrenheit.

(*e.*) Closets should be provided for each sex, entirely separate from each other and having entirely separate means of access. When situated outside the building they should be about fifty feet distant, and should be connected with it by a covered walk. Privy-vaults should be utterly abolished. Movable boxes or buckets should be placed under the seats, and earth or ashes provided as a deodorant. Buckets should be cleaned out at least once a week.

(*f.*) In addition to his other legal powers over schools, the Superintendent of Public Instruction should have authority to oblige school trustees to make improvements or repairs in school buildings for sanitary purposes, whenever the local board of health considers such necessary, and their judgment is supported by that of the State Board of Health.

Reviews and Notices of Books.

Druitt's Surgeon's Vade-mecum. Edited by Stanley Boyd, M.B. London, Assistant Surgeon Charing Cross Hospital, etc. 8vo, pp. 985. Philadelphia: Lea Brothers & Co. 1887.

This well-known manual of modern surgery has now reached its twelfth edition. The eleventh was published in 1877. Surgical progress in the last decade has necessitated an almost complete rewriting of the work, and it is now fully abreast of the times. The chapter on "Diseases of the Eye" has been replaced by a short account of the injuries of that organ, by Mr. A. Quarry Silcock, of the Royal Ophthalmic Hospital.

The ground covered is that of surgery in the widest sense of the word. "To be a good surgeon," the first chapter says, "a thorough general knowledge of medicine and of the sciences upon which the whole healing art is based is absolutely essential." This text has been closely followed, and a valuable condensation of the principles and practice of modern surgery has resulted. Though primarily intended for practitioners, it is a book of the utmost value for students; in fact, one of the best we have ever seen.

Nineteenth Century Sense; The Paradox of Spiritualism. By John Darby. 16mo, pp. 222. Philadelphia: J. B. Lippincott Co. 1887.

One cannot well grasp the contents of this work without having reference to the report of the so-called Seybert Commission. This body of men was requested by the University of Pennsylvania to undertake an investigation of current "spiritualistic" phenomena. The necessary expenses were defrayed from a fund left to the university by a Mr. Seybert. During the time occupied in this work, John Darby was carrying on a similar line of investigation, and this volume is (so to speak) his personal report.

He regards the *personnel* of the commission as being exceptionally good. Though at his time of writing he did not know their conclusions, he evidently thought they were going to harmonize with his own, and this expectation has colored his whole argument. But, as a matter of fact, there is no such harmony. John Darby commences his work with a summary of results obtained by him in a series of spiritualistic *séances*. The "medium" in these was a "Dr. W——," who, curiously enough, was a member of the commission. The report of the latter, to which "Dr. W——'s" name is appended, states that spiritualism, so far as it has come under their notice, "presents the melancholy spectacle of a gross fraud perpetrated upon an uncritical portion of the community." To this "Dr. W——" has given his indorsement, and yet, according to John Darby, he has introduced the latter to a series of facts and experiences which have made of our author a firm believer in spiritualism. It looks very much as if "Dr. W——" was a practical joker, and a pretty clever one at that.

We cannot give a more extended notice here. The book well represents the views of a spiritualist in the best sense. The author's style is good, and his language accurate. His arguments are logical; but we may not agree with his conclusions, because we cannot believe in his understanding of the premises. John Darby is said to be Dr. James E. Garretson.

Dermatitis Venenata. By James C. White, M.D., Professor of Dermatology, Harvard University. 8vo, pp. 216. Boston: Cupples & Hurd. 1887.

The contents of this volume include information concerning the effects of all kinds of irritants of the skin. Titles of chapters are "Pathology," "Plants," "Other Irritants, Organic and Inorganic," and "Animal Irritants"—all with reference to their causative agency in producing the

disease under discussion. The typographical appearance of the book is most creditable. It is exhaustive in its scope, and in all respects commendable.

The Principles of Antiseptic Methods applied to Obstetric Practice. By Dr. Paul Bar, Accoucheur to Maternity Hospital, Paris. Translated by Henry D. Fry, M.D. 8vo, pp. 175. Philadelphia: P. Blakiston, Son & Co. 1887. New York: J. H. Vail & Co.

Dr. Bar is an enthusiast in antiseptic midwifery, as we commonly understand the term. He is, nevertheless, conservative in teaching, and sensible in practice. This work discusses fully the various antiseptic agents used in midwifery, and gives statistics of results obtained in various large maternities. Chapters are included in the main portion of the work on antisepsis in catheterization, in rupture of the uterus, and in the Cæsarean operation; and in an appendix on antisepsis of the umbilicus, and on ophthalmia neonatorum. Dr. Bar follows the Credé method in using nitrate of silver solution, 1–50, immediately after birth. The book, as a whole, is to be commended. It is abreast of the times, and gives complete information concerning the antiseptic procedures incident to every phase of midwifery.

Leçons sur les Fonctions Motrices du Cerveau (réactions volontaires et organiques), et sur l'Épilepsie Cérébrale. Par Le Dr. François Franck. Précédées d'une Préface du Professeur Charcot. Avec 83 figures dans le texte. Pp. 571. Paris: Octave Doin, Éditeur. 1887.

The work embodies a series of experiments and observations extending over ten years, and conducted by Dr. François Franck and Professor Pitres. It forms a comprehensive exposition of the functions of the cerebral cortex and white matter, including the relation of these parts not only to the muscular system, but to the various organs of the body. It is needless to say that the author is a believer in, and teacher of, the doctrine of cerebral localization. We doubt if anyone can read this book and continue any longer sceptical.

Le Charbon des Animaux et de l'Homme. Leçons faites à la Faculté de Médecine de Paris, par I. Straus, Professeur agrégé, Médecin de l'Hôpital Tenon. Avec quatre figures et une planche. Paris: Aux Bureaux du *Progrès Médical*; A. Delahaye et E. Lecrosnier. 1887.

This work consists of a series of fifteen lectures, in which the interesting subject of charbon—its nature, symptoms, prophylaxis, and treatment—is exhaustively treated. The plate shows the microscopical appearances of the blood and tissues containing the anthrax bacillus.

Atlas von Beleuchtungsbildern des Trommelfells, von Dr. Kurd Bürkner, a. o. Professor der Medicin und Director der Universitäts-Poliklinik für der Ohrenkrankheiten zu Göttingen. Jena: Gustav Fischer. 1886.

This atlas consists of fourteen plates, each containing six chromolithographic representations of pathological conditions of the membrana tympani, taken from originals made by Professor Bürkner, of Göttingen. We know of but two similar publications with which the present one may be compared, namely, Politzer's "Beleuchtungsbilder des Trommelfells," containing twenty-four colored pictures of the drum-membrane in health and in disease, and that of James Hinton, containing twenty-four plates of six colored pictures each. With both of these the atlas before us compares very favorably. Furthermore, Politzer's work, in the original, has long been out of print, and Hinton's is so expensive as to place it beyond the reach of most practitioners. Bürkner's work, therefore, is practically the only one of its kind in the market. The plates are very creditable, considering the difficulties which beset any attempt at a reproduction of the coloring of lesions of the lining of the drum-membrane, and we can commend the work heartily.

Beobachtungen ueber Malaria, insbesondere das Typhoide Malariafieber, von Dr. P. Werner, Narwa. Mit zwei lithographirten Curventafeln. Berlin: August Hirschwald. 1887.

This book contains about all that there is to say upon the symptomatology, complications, and prognosis of malarial fever. Concerning treatment we do not find a word written, but our German brethren always seem to regard that as something of secondary consideration. The book, however, makes no pretension of being a complete treatise, and, as far as it goes, it is useful and instructive.

Pulmonary Consumption; its Etiology, Pathology, and Treatment, with an Analysis of 1,000 Cases to Exemplify its Duration, and Modes of Arrest. By C. J. B. Williams, M.D., LL.D., F.R.S., Fellow of the Royal College of Physicians; Physician-extraordinary to her Majesty the Queen; Senior Consulting Physician to the Hospital for Consumption and Diseases of the Chest, Brompton; formerly Professor of Medicine and Physician to the Hospital, University College, London. And by Charles Theodore Williams, M.A., M.D. Oxon., Fellow of the Royal College of Physicians; Physician to the Hospital for Consumption and Diseases of the Chest, Brompton. Second Edition, enlarged and rewritten by Dr. C. Theodore Williams. With four colored plates and ten wood-cuts. Philadelphia: P. Blakiston, Son & Co. 1887.

It is a real pleasure to see another book bearing upon its title-page the name of Dr. C. J. B. Williams. The first edition of this work appeared so long ago that it is unknown to the younger generation of physicians, and the present edition is therefore practically a new treatise. The author is probably the oldest living medical writer, his "Practice of Medicine," once a standard work, having been published in 1843. In the present work two chapters remain practically unchanged, but the remaining chapters either have been revised by Dr. C. T. Williams, in order to bring the teaching fully up to date, or are wholly new. The subject of pulmonary consumption has been most comprehensively considered in all its aspects, and the work leaves little to be desired by anyone seeking the latest knowledge concerning this subject, than which there is none more important in the whole range of medicine. Considerable space is devoted, as it should be, to the question of treatment, prophylactic, medicinal, and climatic, and a liberal use has been made of the clinical notes of the Drs. Williams, father and son, in the sections on symptomatology and therapeutics. We are glad to be able to warmly recommend this work to practitioners and students alike.

Prize Essays of the American Health Association. 8vo, pp. 198. Printed at Concord, N. H. 1886.

This is the second edition of these essays, the prizes for which were presented by Mr. Henry Lomb, of Rochester, N. Y. The titles and authors are as follows: "Healthy Homes and Foods for the Working-classes," by Professor Victor C. Vaughn, of Michigan University; "The Sanitary Conditions and Necessities of Schoolhouses and School-life," by D. F. Lincoln, M.D., Boston, Mass.; "Disinfection and Individual Prophylaxis against Infectious Diseases," by George M. Sternberg, M.D., U. S. A., and "The Preventable Causes of Injury, Disease, and Death in American Manufactories and Workshops, and the best Means and Appliances for preventing and avoiding them," by George H. Ireland, Springfield, Mass.

Health-resorts at Home and Abroad. By M. Charteris, M.D., Professor of Therapeutics and Materia Medica, Glasgow University. Second edition. London: J. & A. Churchill. 1887.

This handy little volume contains a description of a number of health-resorts in England and on the Continent of Europe, and will be of service to the traveller who desires to inform himself of the principal characteristics of the different waters, and of the indications for treatment at the various European spas and other health-resorts. There is a good map, and also a comparative table of the drugs in the British and Austrian pharmacopœias which may be found useful upon occasion.

The Treatment of Hemorrhoids by Injections of Carbolic Acid and other Substances. By Silas T. Yount, M.D., Physician of St. Elizabeth's Hospital, Member American Medical Association, etc. LaFayette, Ind.: The Echo Music Co. 1887.

The title of this little brochure sufficiently explains its contents. One who does not know how to treat hemorrhoids may glean some valuable information from this book.

Transactions American Laryngological Association. Eighth Annual Meeting, 1886. 8vo. Pp. 230. New York: D. Appleton & Co. 1887.

Twenty-five papers is the record for the session of the laryngologists in 1886. They are of a uniform high order. The volume is attractive in appearance.

Transactions of the New York Odontological Society, 1886. 8vo. Pp. 152.

This is a most creditable volume in appearance and contents. New York dentists seem fully abreast of the times. Many of the papers are of interest to physicians as well.

Geschichte der Laryngologie, von der frühesten Zeiten bis zur Gegenwart. Von Dr. Gordon Holmes. Aus dem Englischen übersetzt von Dr. Otto Koerner. Berlin: August Hirschwald. 1887.

This is the German translation of Dr. Holmes' History of Laryngology, which appeared first in the *Medical Press*, July to September, 1885. The translator has added some references not found in the original.

The Autobiography of Samuel. D. Gross, M.D., D.C.L. (Oxon.), LL.D., Cantab., Edin., Emeritus Professor Surgery, Jefferson Medical College, Philadelphia, with Sketches of his Contemporaries. Edited by his Sons. In 2 vols. Philadelphia: George Barrie, Publisher. 1887.

Autobiographies, as a rule, are not interesting; neither are they often instructive. The writer, for one reason, is apt to be a trifle partial in his treatment of the subject. He views matters with a short focus, and naturally small matters are magnified out of proportion. He loses the perception of the eternal fitness of things. In Dr. Gross' autobiography these general objections are reduced to a minimum. In fact, the reader of these volumes is apt to get more in love with the subject of the sketch than the writer himself. It is the most interesting and instructive work of its kind that we have read for a long time. The author takes you into his inner confidence, and you live over with him a life full of interesting incident, and learn to appreciate the true value of patient labor, guided as it was by high and honorable motives. His inner life, which is presented in his reflections, gives an insight into a purity of personal character which is refreshing to contemplate. The style is simple, easy, and entertaining. His sketches of his contemporaries are comprehensive and truthful, and add not a little to the general good character of the work. Altogether, it is a charmingly written and thoroughly entertaining book, and no practitioner can read it once without wishing to look over it again, and each time feel the better and wiser for so doing.

Die Massage in der Gynäkologie. Von Dr. Paul Profanter, gew. Operateur an der II. geburtshilflich-gynäkologischen und I. chirurgischen Universitätsklinik zu Wien, Brunnenarzt in Franzensbad. Mit einer Vorrede des Herrn Geheimrath Professor Dr. B. S. Schultze in Jena. Mit 34 Abbildungen. Wein: Wilhelm Braumüller. 1887.

Massage in Gynæcology. By Dr. Profanter. With a Preface by Professor Schultze.

This work is made up chiefly of the histories of sixteen cases of parametritis, oöphoritis, endometritis, malpositions of the uterus, etc., treated by massage, according to Brandt's method, in Schultze's clinic at Jena. The mode of treatment is fully explained in the body of the reports. The results, as here shown, were excellent and appear to demonstrate the utility of the method. In the preface Professor Schultze speaks in the highest terms of the value of the procedure in appropriate cases. A number of wood-cuts serve to depict graphically the pathological conditions and the results of treatment.

L'Enseignement Actuel de L'Hygiène dans les Facultés de Médecine en Europe. Par le Dr. W. Lowenthal. Professeur Agrégé à l'Académie de Lausanne. Paris: H. Le Soudier. 1887.

Instruction in Hygiene in the Medical Schools of Europe. By Dr. Lowenthal.

The book before us was written in the laudable attempt to stimulate the different universities in Europe to greater activity in teaching hygiene. The author first presents a list of the universities in Europe, with a statement of the attention which is paid in each to instruction in this important science, and then proposes means whereby needed improvements could be made. The necessity of such instruction needs no argument, and that it is neglected too much in Europe, as well, though perhaps not to as great an extent, as in this country, is made evident by this painstaking work of Dr. Lowenthal.

Leçons de Clinique Chirurgicale. Par Terrillon, Agrégé de la Faculté de Médecine, Chirurgien de la Salpétrière. Rédigées par M. le Dr. Routier. Paris: A. Delahaye & E. Lecrosnier. 1887.

Lessons in Clinical Surgery. By M. Terrillon.

This is a series of thirteen clinical lectures delivered by Professor Terrillon. The subjects treated of are: cold abscesses, cicatricial stenosis of the œsophagus, lymphadenoma of the neck, various forms of local tuberculosis, etc. The lectures are pleasant to read, and are also full of sound advice and practical instruction.

Transactions of the Association of American Physicians—First Session, June, 1886. Vol. I. James T. Whittaker, M.D., Recorder. 8vo. Pp. 261. Philadelphia: William J. Dornan. 1886.

The inaugural volume of the "Transactions" of this recently organized association is a most creditable one. Its appearance and contents are alike attractive. The number of papers published is nineteen, and they are all valuable contributions to scientific medicine. The Record has already commended the sound and sensible ideas expressed—as to the aim of the Society—by its first President, Dr. Francis Delafield: "We want an association in which there will be no medical politics, and no medical ethics; an association in which no one will care who are the officers and who are not; in which we will not ask from what part of the country a man comes, but whether he has done good work and will do more; whether he has something to say worth hearing and can say it."

PATHOLOGY AND TREATMENT OF GONORRHŒA AND SPERMATORRHŒA. By J. L. MILTON, Senior Surgeon St. John's Hospital, London. 8vo. Pp. 474. New York: William Wood & Co. 1887.

THE portion of this book devoted to gonorrhœa occupies three hundred pages. It has been previously put forth in earlier editions, of which the present is an abridgment. There are added also various papers which have appeared in journals. The chapters on gonorrhœal affections of the serous membranes, heart, and cord-membranes, together with those on gonorrhœal pyæmia and pyelitis, appear for the first time.

The views advanced on pathology contain nothing essentially new. The occurrence of the disease in the female receives considerable discussion. Mr. Milton does not commit himself as to the causal relation of the gonococcus to the malady. The great value of this first section of the work lies in comparisons of results attained by the various methods of treatment, and that, too, not in a vague, general way, but with definite statistics given, from which logical conclusions can be drawn of clinical effects. The chapter is a very exhaustive one.

The section on spermatorrhœa is also very complete. The author denies that this trouble is a mere symptom, arising principally out of a morbid imagination. He regards it as a distinct disease. Separate chapters are devoted to mere loss of seminal fluid and to true impotence. An ingenious apparatus is described for the prevention of nocturnal erections and emissions. On the penis, at bedtime, is placed a ring, so made that when expanded by an erection it completes an electric curcuit, and, by means of wire connections, rings a small alarm-bell placed under the patient's pillow; he is at once aroused, and can thus prevent any further genital excitement. We are not told that this ingenious device is any better than more simple and by far less cumbersome means.

Throughout the entire volume the ideas of others receive courteous consideration at the hands of the author, who writes sensibly and to the point. His own convictions are nowhere unpleasantly obtruded. The book is to be commended.

WHAT TO DO IN CASES OF POISONING. By WILLIAM MURRELL, M.D., F.R.C.P., etc. American edition, edited by Frank Woodbury, M.D., Philadelphia. 12mo. Pp. 158. Philadelphia. The Medical Register Co. 1887.

DR. MURRELL'S little work has reached its fifth edition in England. The successive issues have kept up with the times, and it is undoubtedly the best book of its kind extant. The present edition contains a few words on the "fee," which, the author thinks, should range from ten to one hundred dollars "according to the circumstances and social position of the patient." The "specialist," in poisoning cases, may collect from one hundred and twenty-five dollars to double that sum. The title of the book gives a sufficiently definite idea of its contents.

DISEASES OF THE HAIR AND SCALP. By GEORGE THOMAS JACKSON, M.D., Instructor in Dermatology New York Polyclinic, etc. 8vo. Pp. 356. New York. E. B. Treat. 1887. Price, $2.75.

THIS work is a most creditable addition to American medical literature. The author states that five years ago "he was in need of some complete treatise upon diseases of the hair, and finding none of recent date excepting such as were rather of a popular than of a scientific character, he began those studies which have resulted in the present volume."

The book is arranged as follows: Part I. treats of the anatomy, physiology, and hygiene of the hair, and hygiene of the scalp; Part II., of the essential diseases of the hair; Part III., parasitic diseases of the same; and Part IV. of diseases of the hair secondary to diseases of the skin. An extensive bibliography and an index of journal literature are appended. The latter is mainly confined to articles which have appeared since 1860. Numerous well-executed illustrations are scattered through the pages. The author's style is clear and concise. He wastes no time in profitless discussion. He has written a *working* book, and is to be congratulated on his success.

PRACTICAL URINE TESTING. By CHARLES GODWIN JENNINGS, M.D., Professor of Chemistry, Detroit Medical College. 12mo., Pp. 124. Detroit: D. O. Haynes & Co. 1887.

THIS manual is neither better nor worse than a number of similar publications which have recently appeared. It is concise, yet complete. Its tabulated form and its general typographical arrangement are commendable.

ATHOTHIS: A SATIRE ON MODERN MEDICINE. By THOMAS C. MINOR. 12mo. Pp. 194. Cincinnati: Robert Clarke & Co. 1887.

THIS is a novel written in a light vein and yet not without considerable humor. It makes some rather keen thrusts at the "fashionable" practitioners of these latter days, and is an amusing book for a spare hour.

PHYSICIAN'S POCKET REGISTER AND PHYSICIAN'S OFFICE REGISTER. By ADOLPH BERND. St. Louis: Henry Bernd & Co. 1887.

THESE books are constructed upon the usual model for such publications. The Pocket Register provides for three hundred accounts, each for an entire year. It is a combination of visiting list, journal and ledger; is not too bulky, and is elegant in general make-up.

The Office Register is a large volume, twelve by seventeen inches. It is well indexed. The account of a patient for an entire year is contained within three inches. It will hold nearly six hundred and fifty separate accounts.

STRICTURE OF THE URETHRA. By E. DISTIN-MADDICK, F.R.C.S. Edin., late Surgeon Royal Navy. 8vo. Pp. 154. London: Baillière, Tindall & Cox. 1887.

THESE pages contain a great deal of common-sense. They cover the usual topics naturally suggested by the subject of urethral stricture. The author is inclined to be at times slightly satirical, but his conclusions are sound. He does not regard true stricture as being so frequent as is generally believed. He thinks that the indiscriminate passage of instruments in urethræ—the seat of tenderness after inflammation—is in itself a frequent cause of stricture. In practice he vastly inclines to dilatation over cutting methods, and brings out on nearly every page the absolute necessity of avoiding force in manipulation. He makes very caustic criticisms on the shortcomings of surgeons as regards this latter point, and maintains that medical men often harm more than benefit their patients. Valuable remarks are made concerning the "natural obstructions" in the urethra, and how they are often confounded with stricture. In examining for the latter, he strongly urges, in case the stricture be a light one, the use of a "conductor" to guard the canal against injury, and to "thread the stricture," as it were, with a fine bougie or catheter. A conservative position in regard to treatment is taken throughout. The author has written from the stand-point of the patient as well as from that of the surgeon, and has been commendably successful in his task.

IMMEDIATE RELIEF FOR LUMBAGO.—Dr. Burggraeve recommends painting the painful parts with the following: ℞. Tr. iodinii, collodii, aq. ammoniæ, āā ʒss. M.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 3, 1887.

A. Jacobi, M.D., President, in the Chair.

The Statistical Secretary, Dr. Judson, announced officially the deaths of James Knight, M.D., and William M. Chamberlain, M.D.

Dr. Joseph D. Bryant then read a paper (see p. 613) entitled

HOW CAN THE MEDICAL PROFESSION AID THE BOARD OF HEALTH?

The discussion was opened by Dr. E. G. Janeway, who was of the opinion that the medical profession could aid the Board of Health very largely, and that the suggestions made in the paper covered a great share of the ways in which such aid could be extended for the benefit of the city, especially with reference to contagious diseases. There were two important factors which had prevented the profession from giving the Board the aid it might have done—namely, forgetfulness and lack of attention to the subject. It might

SEEM TO BE A SMALL MATTER

that a case of this or that disease should not be reported, and it might be simply a question of lack of attention at the time. Sometimes there might seem to be no necessity for making such report, but the deleterious consequences which followed this neglect might at the same time be very great.

From the scientific standpoint, accurate statistics concerning contagious diseases could never be obtained until the profession united in reporting every case of these diseases to the Board of Health, where they could be properly recorded, and the records made accessible for reference. Such information was highly desirable.

An illustration was cited that showed the remarkable facility with which an eminent member of the profession failed to give a satisfactory death certificate, and sometime afterward sent an exceedingly uncomplimentary letter with reference to the deficiency in the statistical information that could be furnished by the department.

CONTROL OF CONTAGIOUS DISEASE

could come only from knowledge of the localities where it prevailed. The recurrence of *variola* in this city had, on several occasions, come from unreported cases.

Dr. Janeway then spoke of the relationship between contagious diseases and the public schools, and said it was absolutely essential that there should be some place to which information could be sent, and from which it could be distributed for the benefit of the public. The Board of Health was the established authority to take charge of such information.

The profession could aid the Board of Health by its statements and advice given to families; and by neglecting to give such aid a great deal of harm could be done, whereas by affording it a great deal of good could be accomplished. If a member of the profession said to the family there was no special harm from a case of this or that disease, and poohpoohed the regulations of the Board, much harm could be done in more directions than one, whereas great benefit would attend the influence of his professional support.

AS REGARDS VACCINATION,

it had been the means of reducing the proportion of cases of small-pox to a marked extent, and all the permissive and persuasive vaccination possible should be performed. Here, again, it was very easy to defeat, largely, the efforts made by the Board of Health, and chiefly through two avenues—namely, the statement by members of the profession that the virus used was bad, and that there was great danger of contracting syphilis by the inoculation.

Such remarks might seem very trifling, but they prevented vaccination from being accepted, and he believed it to be

UNWISE TO ADD MEMBERS OF OUR OWN PROFESSION

to the category of antivaccinationists.

Again, very important aid could be given to the Board of Health by reporting to it, whenever and wherever seen, *defective house building*.

Dr. A. N. Bell, on invitation, continued the discussion, and spoke particularly of the premonitory symptoms of grave diseases, such as diphtheria, scarlet fever, pneumonia, etc., that arose from bad plumbing. If physicians would interest themselves, and direct their attention more closely to all the conditions in the surroundings of their patients, such fatal diseases, in many instances, could be anticipated and prevented. The Board of Health was not able to inspect all the houses in the city of New York where, up to the date of the enactment of certain laws, the plumbing was notoriously bad, and its attention, therefore, might not be directed to this deficiency until some contagious or infectious disease made its appearance. Physicians could call the attention of the Board to these conditions of deficient plumbing and ventilation as evidenced by the symptoms of which the residents in these houses complained, and in that way render the Board important aid and the people lasting benefit.

Dr. Bell also spoke of

THE EVILS OF OVERCROWDING.

Dr. A. H. Smith thought that the proceedings of the evening marked the advent of a new era; for it was an almost unheard of occurrence that the Health Department should come before the medical profession and ask for its co-operation. It had always seemed to him that the health board of any city should derive its experience from the medical profession, instead of being a body organized without reference to that profession. Without such assistance, the board was without that sympathy essential to the proper performance of its work.

Dr. C. R. Agnew took an active part in the organization of the Metropolitan Board of Health, and had felt and exercised the interest of an amateur sanitarian from that date up to the present time. He believed that the presence of Dr. Bryant, Health Commissioner, and his paper would lead to the cultivation of such relations as should exist between this representative of municipal hygiene and the general profession.

All should hail any movement which would increase the scientific reputation of the Board of Health, and he, therefore, foresaw excellent results from the appointment of so competent men as Dr. Prudden and Dr. Briggs as pathologists to the department.

The city of New York, with its climate, soil, and social conditions, could furnish the best field in the world for the enthusiastic sanitarian to work in, and the best results of such work could be effectually realized by fraternal co-operation between the profession and the Health Department.

Mr. James C. Bayles, President of the Board of Health, was invited to make some remarks, which he accepted as a great personal compliment. When he was placed at the head of the department he soon learned that there was no evidence that there was such a thing as a medical profession, and he was completely at a loss to know how he could ascertain its relations to the Board of Health. But, happily, the problem had been solved through the efficient aid of Commissioner Bryant. Among the first things he did, after being placed in his official position, was to hold a consultation with the plumbers, whom he found not only willing, but desirous, to co-operate with the Health Department in the adoption of rules which should render their labor most satisfactory, from

the sanitary point of view. The result of the meeting was that the rules were so amended that the code of plumbing was as much better than the old code as the old code was better than no code at all.

A very important aid which could be rendered was a defence by the medical profession of

THE POWER OF THE BOARD FOR GOOD.

The influence upon the City Government and the Board of Estimates and Appropriation depended largely upon the sympathy and co-operation extended to the Board of Health by the medical profession, and to do its best work those appropriations were essential. Almost any amount of money could be obtained, which could be used for the benefit of the public and the protection and care of the city, if the medical profession would unite in making the demand.

THE PRESIDENT OF THE ACADEMY spoke of vaccination, and hoped that it might become compulsory. He also referred to the Willard Parker Hospital for the reception of cases of contagious diseases from tenement-houses. He expected that the time would come when there would be several such hospitals in the city, and requested that the gentlemen connected with dispensaries would see that such cases were given into the charge of the hospital at the foot of East Sixteenth Street, where they would have better accommodations than could be afforded them in their homes.

With regard to the conference committee suggested in the paper, he would ask Dr. Bryant to state what, in his opinion, would be the scope of the duties of such a committee.

DR. BRYANT said that the duties of the committee would be to act when the Board of Health shall request, when the medical profession shall request, and when they shall request each other.

DR. ELLSWORTH ELIOT said that many did not like the notoriety incident to the fact that measles, or scarlet fever, or diphtheria, was in their houses. As an illustration, he cited several instances, and among them one where the father asked what the fine was for not reporting the case, and when told that it was fifty dollars, said, "not report it, and he will pay the fine." Milliners, grocers, and others in business which necessitated the visits of customers, were usually very much annoyed by the fact that the presence of either of these diseases in their houses became known, and he would ask that the Board of Health injure business in such cases to the least possible extent.

He asked how, in an urgent case, the patient could gain admission to the Willard Parker Hospital? Was it obligatory to first notify the Board of Health and await the delay that necessarily attended that mode of procedure?

How could a patient sick with typhoid fever be transferred to North Brothers' Island?

DR. BRYANT said that patients were received at the Willard Parker Hospital direct, without the preliminary notification of the Board of Health.

To have a patient sick with typhoid fever transferred to North Brothers' Island, notify the Board of Health, and comfortable conveyance would be furnished by either coupé or ambulance to the steamboat, and at the landing at the island there would be ample and comfortable modes of conveyance from the boat to the wards of the hospital. All the hospitals in the city, however, receive patients sick with typhoid fever.

DR. ELIOT moved that a

COMMITTEE OF CONFERENCE,

consisting of five members, be appointed by the President, at his convenience, to co-operate with the Board of Health, and that the President, Dr. Jacobi, be a member of the committee. Carried.

DR. H. W. BOONE, Professor of Surgery in the Medical School in Shanghai, China, was then introduced. He spoke of the sanitary condition of that city, of the absence of any attempt to prevent the entrance of cholera, where the disease was endemic. He also spoke of the work being done in the medical school with which he was connected, and of the effort being made to build up a

MUSEUM AND LIBRARY.

He asked for contributions for this purpose, and said that donations of specimens or books could be sent, at any time, addressed to him, 22 Bible House, New York City, where they would be promptly forwarded to Shanghai.

The Academy then adjourned.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, October 7, 1887.

GEORGE F. SHRADY, M D., PRESIDENT, IN THE CHAIR.

DR. WILLIAM H. DRAPER read a paper in which he reported two cases of

ACUTE TRANSVERSE MYELITIS,

with remarks.

DR. G. L. PEABODY demonstrated the lesions microscopically. There were no ganglion cells in the anterior horns. In some of the sections the anterior horns were so diffluent that they could not be preserved. The white matter had been invaded to a considerable extent by round cells.

DR. DRAPER asked if any gentleman present had met with a case of transverse myelitis, such as one of his, with ulceration of the mucous membrane of the stomach.

DR. PEABODY had examined the ulcers in Dr. Draper's case, but found only evidence of intense inflammation about their edges.

DR. C. L. DANA remarked that it was not uncommon for acute myelitis to come on like a hemorrhage, and then it was supposed to be accompanied by minute hemorrhages.

DR. PEABODY said the cases were interesting with reference to the uncertainty of etiology. It occurred very frequently in non-syphilitic persons. The occurrence in some cases, as in one of these, was so very sudden that it would seem it must be due to some sudden disturbance of the blood-vessels. In Dr. Draper's second case, he had supposed that the disease was due to hemorrhage, until he made the autopsy and found that there was none.

DR. ANDREW H. SMITH asked if it was not recognized that softening of the cord might exist without giving rise to distinct symptoms, until it had progressed to a certain degree, when suddenly the continuity of its action ceased, and symptoms developed abruptly.

DR. PEABODY remarked that Dr. Putnam, of Boston, had expressed very much the same view which Dr. Smith had just suggested.

DR. C. L. DANA thought it was unnecessary to invoke any preceding disease to explain the sudden development. The sections which he had seen showed that the lesions commenced as an acute anterior poliomyelitis, and then, instead of pursuing the ordinary course of stopping and getting well, it progressed rapidly. The polio-myelitis of infants was known to come on rapidly. Dr. Dana referred to cases reported by Tietsen, in which, with the symptoms of acute transverse myelitis, there was nothing found except slight congestion, with proliferation of cells, but no acute inflammation. That writer suggests that it was due to either thrombosis or embolism, or sudden reflex contraction, which caused local asphyxia of the cord. In the cases under demonstration there was no doubt that the lesion was inflammatory.

DR. DRAPER remarked, with regard to the hypothesis proposed by Dr. Smith, that in the first case the disease

began very gradually. It seemed to him hardly possible that any distinct changes could take place in the cord without producing symptoms; he thought it was entirely untenable. The theory had been suggested that acute transverse myelitis was an infective process. He did not know that any examinations had been made to either develop or confirm this idea; but it seemed to him that the theory of thrombosis, dependent upon infection by cocci, might explain as well as any other the majority of the cases of so-called ordinary acute inflammatory softening.

THE TEGUMENTARY LESIONS

in both cases had interested him. In the first they were confined to the skin, and in the second case they were found in the mucous membrane of the stomach. They demonstrated that these lesions were not necessarily due to pressure, but were undoubtedly dependent upon trophic disturbances.

Dr. Andrew H. Smith asked whether these lesions were secondary to the spinal lesion or the result of the same cause, on the assumption that there was embolism.

Dr. Draper said he supposed that they were consecutive, and not dependent upon any localized infection.

Dr. Smith asked if the same cause might not operate at all these situations.

Dr. Draper said it might; yet in the first case the onset of the eruption was distinctly urticarial in character, and he supposed that it was due to vaso-motor disturbance.

HEMI-EPILEPSY.

Dr. Andrew H. Smith had just seen a hospital case, which was apparently one of hemi-epilepsy. The patient was a young man, with a slight cardiac lesion and considerable anæmia. He was attacked suddenly with convulsion, confined to the right side, lasting about the time of an ordinary epileptic seizure, recurring at intervals of about forty-five minutes, beginning in the hand, extending to the arm, and thence to the leg, which was more affected than the arm. There was no loss of consciousness; indeed, the patient was able to describe his sensations while the attack was on. The seizure passed off with intense burning pain, especially in the hands. There was nothing that pointed to gross cerebral lesion. The pupils were widely dilated, did not react to light, were equally affected, and remained so during the intervals. Nothing had been ascertained concerning the temperature. The idea that the case was hysterical in character he thought was untenable.

VOMITING AND CEREBRAL DISTURBANCE AFTER ANÆSTHESIA WITH ETHER.

Dr. Sexton asked for the experience of the members with regard to nausea or vomiting, or cerebral disturbance after ether anæsthesia; their duration and character, and in what proportion of cases either occurred.

Dr. William T. Bull thought it was the general experience of surgeons that the subsequent effects were very much influenced by the condition of the stomach at the time the ether was administered. If the stomach was empty, it was exceptional for vomiting to occur more than once or twice after the patients had recovered from the anæsthesia. He had not met with a case of persistent vomiting after the use of ether, and he thought that such cases were comparatively rare. It occurred much less frequently after ether than after chloroform, and that was one of the objections to the use of chloroform. He had not met with cerebral disturbance more serious than transitory headache.

He had seen one case, however, of functional disturbance which was not so very exceptional. Recently he saw the statement in one of the English journals that such disturbance was not at all uncommon. The case which he saw was one in which ether was given for an operation to rectify a displaced uterus, and it was followed by complete insanity for four days, when the patient suddenly came to her normal mental condition.

Dr. Weir had not had any cases in which either gastric or cerebral disturbances had been marked after the administration of ether. He believed it to be well founded that vomiting was more likely to occur when there was food in the stomach than when empty at the time the ether was administered.

Dr. Shrady had never met with persistent vomiting after either, nor with any cerebral disturbance that could be referred to the anæsthetic.

Dr. Sexton said he had been led to ask the question because of a case he had recently seen in which vomiting persisted for days, attended by vertigo and difficulty in walking. The patient had been an epileptic and was anæmic.

Dr. A. B. Ball related a case in which the patient, a woman in the eighth month of pregnancy, suddenly had a severe attack of

DYSPNŒA,

in which the breathing was very peculiar. The history was that three nights ago she slept with the window wide open, awoke feeling rather chilled, and on the next day she had considerable muscular rheumatism in the right shoulder, arm, and back, with some backache. The physician who was called in examined her chest, but did not detect any evidence of either pulmonary or pleuritic trouble. On the following day she was apparently quite well, except that she complained of soreness, and on the day following she came to the city. She slept very well during the night, and went out this morning, and while visiting at the house of a friend she was attacked with difficulty of breathing which was quite alarming. When Dr. Ball arrived the attack had passed off partially. There was no fever, the pulse was regular and a little quick, and nothing abnormal was found on auscultation. While sitting by the side of the patient she had another severe attack, in which respiration was confined entirely to the thoracic muscles, was shallow and rapid, unaccompanied by pain, but attended by a sense of constriction around the body at about the level of the diaphragm. The uterine tumor did not press at all upon the diaphragm. The entire aspect of the case impressed him with the idea that it was one of

SPASM OF THE DIAPHRAGM.

He did not observe any retraction of the parietes in the region of the diaphragm. He immediately gave her a hypodermic injection of morphine. The attack did not last more than five or six minutes. During the next hour she had two or three attacks, and he gave her more morphine, and since then an attack had not occurred, but the patient complained of soreness at about the level of the diaphragm. There was no evidence of ordinary pleurisy. Her health during pregnancy had been remarkably good. During the attacks of difficulty of breathing she did not become at all cyanotic. The respirations were increased in frequency to probably fifty or sixty to the minute.

Dr. Draper recalled a case in which the patient had a great variety of hysterical symptoms. The breathing was rapid and shallow, about eighty to the minute. She had two or three attacks of that kind, which at first seemed to be very alarming, but he concluded that it was a case of

RESPIRATORY NEUROSIS IN A HYSTERICAL WOMAN.

Dr. Ball said that his patient was not hysterical in the ordinary sense of the term, and that these attacks were attended by extreme distress. It was her second pregnancy, and there were no nervous symptoms during her first pregnancy.

Dr. G. L. Peabody related a case of

POISONING BY ILLUMINATING GAS.

A negress, sixty-five years of age, was brought into the New York Hospital on Sunday morning. She had been

found comatose in her bedroom, having accidentally turned the stop-cock of the gas-fixture *all the way round.* When admitted she was absolutely comatose, pulse 150, respiration deep, full, and regular. Inhalations of oxygen subcutaneously. During the forenoon she improved, but when Dr. Peabody saw her in the afternoon the patient was still comatose, although the muscles of the face could be made to respond to external irritation. The stimulants and oxygen were continued. On the next day she was partially conscious, and recognized the house-physician. The oxygen was discontinued. There was not any very marked redness of the mucous membrane, as sometimes is seen. There was no cyanosis, except at first; there was no frothing at the mouth. During the day (Monday) she continued to improve apparently, but when he saw her on Tuesday the patient had distinctly retrograded, had again become comatose; her pulse had risen to 150 or 160; she swallowed with difficulty, and it was absolutely impossible to arouse her. Dr. Peabody then

BLED HER

to the extent of *twenty ounces.* The oxygen was ordered to be given for ten minutes every hour, and the stimulants to be kept up actively. About three hours afterward the patient had improved so much that it did not seem necessary to resort to transfusion. That night she again became conscious, steadily improved, and had since done well.

Dr. Draper remarked that the plan of blood-letting had been resorted to a number of times in the New York and Chambers Street Hospitals, and it seemed to have resulted in good effects in each case.

Dr. Peabody remarked that there was nothing peculiar in the appearance of the blood taken in the case just narrated. He performed venesection on one other patient, bled the man freely, and he made a good recovery.

Dr. Andrew H. Smith referred to a case that pursued a chronic course, with alternations of unconsciousness and improvement, and in which it was two weeks before the recovery was complete.

The Society then went into executive session.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 28, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

Dr. Mary Dixon Jones presented

THE OVARIES AND TUBES

removed from a married woman who had had one child and one miscarriage. After the latter she was confined to her bed for five months with probable septic peritonitis. Ever since that time she has suffered from more or less pain in the lower part of the pelvis, which, during the last five months, had been very severe.

The right Fallopian tube was about the size of a hen's egg, was completely closed, all traces of fimbriæ gone, and it was universally adherent, but especially to the posterior part of the uterus, with old and strong adhesions. The right ovary was very thin, and contained bone. There were several parovarian cysts which ruptured during the operation, and there was considerable hemorrhage. The abdominal cavity was washed out with a bichloride solution—1 to 50,000—the peritoneum was united with continuous catgut suture, and the abdominal wound was closed with silk. Reaction did not take place for seven hours. On the second day the drainage-tube was removed. On the third day the temperature was normal, and the patient has since been doing well.

Dr. Jones presented a second specimen of the uterine appendages removed from a woman twenty years of age, who suffered severe pain for six or eight days before each menstrual period, which lasted ten days. Dr. Polk saw the patient in consultation, and recommended removal of the tubes and ovaries, which were evidently very much diseased. Laparotomy was performed, with the assistance of Dr. A. M. Jacobus. Some of the adhesions were so firm and extensive that it became necessary to ligate them, and then divide them with the knife. Both pedicles were very large; they were secured with ligatures, and cauterized. Both tubes were closed. The drainage-tube was employed. This patient was put to bed, and her symptoms disappeared, and yet at the operation the extensive disease was found as shown in the specimens, which were liable to rupture at any time, and give rise to serious complication, if not fatal result. She did not approve of attempting to support the appendages by means of a pessary, neither had she seen a case in which cerebral congestion had been produced by suddenly stopping menstruation.

Dr. Carpenter asked Dr. Jones how many cases she had seen in which pyo-salpinx ruptured previous to operation.

Dr. Jones had seen *one* that was proven by post-mortem.

Dr. Boldt had met with *six* cases.

Dr. A. P. Dudley had encountered *one* case.

Dr. Ferguson had made a post-mortem examination in *one* case.

Dr. H. J. Boldt exhibited

AN INTUBATION-TUBE THAT HAD AROUND ITS HEAD AN INCRUSTATION OF CALCAREOUS MATERIAL.

He thought it possible that, in some cases, ulceration might be produced by such a deposit around the upper part of the tube. The case in which it was used was an apparently hopeless one, but the child made a fairly good recovery.

Dr. Wyeth mentioned recent statistics, published by Dr. Stone in the *Pittsburg Medical Review*, of thirty-two cases of intubation, with twenty-one deaths, and the writer concluded by condemning the method.

Dr. W. P. Northrup had seen a tube that had been in the œsophagus fifty-two hours, and was covered entirely with a deposit similar to that seen upon Dr. Boldt's tube. In that instance it was accounted for by the fact that the bichloride of mercury had been used in the treatment of the case. He had never seen an ulcer at the head of the tube that did any harm. The ulcer which did harm was at the lower end of the tube, and upon the anterior wall of the trachea.

The tube was referred to the Committee on Microscopy for examination and report as to erosion of its surface and precipitation of lime salts, lime-water having been used in the treatment of the patient.

Dr. A. P. Dudley presented a specimen of

MALIGNANT (?) DISEASE OF THE OVARY,

with the following history: Annie D——, single, thirty-four years of age, and always healthy; menses regular, and lasting one week, until last February, when the menses began to appear every two weeks and remain six days. She never had any pain with the menses or otherwise until March, when she was troubled with gravel, and micturition was attended with great pain and the passage of small quantities of urine. The gravel disappeared about the middle of April. She then began to have pain in the right inguinal region, which continued to be very severe, and lasted until about the first of August, when it changed to the character of a weight in the abdomen. The menses continued to appear twice monthly until the 6th or 7th of July, when they lasted only two days. In August there was only a show. She first noticed "a bunch" in the right side about the first of April. It increased in size very rapidly, and was attended by the pain, as previously mentioned; she lost flesh rapidly during the past three months, and when seen by me, August 25th, she presented the typical *facies ovariana.*

Examination at that time revealed a large tumor in the abdomen, giving to the touch the impression of a multilocular ovarian cyst with thick walls and contents. It was quite movable from side to side, but not from above downward—the greatest portion of the tumor being to the left of the median line of the abdomen, and the upper portion seemed quite hard.

A DISTINCT PERCUSSION WAVE COULD BE OBTAINED.

Digital examination showed the hymen intact, vagina normal, and womb pressed forward against the pubes No sound was introduced into the organ. The left culde-sac was occupied by a hard portion of the growth. No bimanual percussion could be obtained considering the duration of the growth and its size. He anticipated finding *malignant* disease, and so stated to her physician; operation advised as early as possible. She entered St. Elizabeth's Hospital at once, and the operation was made on August 31, 1887. Incision three inches long, through linea alba. The peritoneum was found thickened to one-eighth inch anteriorly. The whole anterior surface of the growth was adherent to the anterior abdominal wall. This was stripped off; no ascitic fluid escaped. When tapped, the growth proved to be multilocular, with the cysts containing widely differing contents—some jelly, some clear limpid fluid, some a cheesy matter, and some blood. Great care was taken not to allow any of the contents of the tumor to enter the general peritoneal cavity. The growth had a long pedicle, which was easily ligated. The right ovary was found to be the size of a small orange, cystic and adherent, with corresponding tube some enlarged; both were removed. She rallied quickly from the shock, aided by rectal injections of brandy and water. There was nothing worthy of mention concerning the after-treatment, except that the temperature never went above 101½° F. (next day), and the pulse never above 107. She left the hospital on Monday, September 26, 1887, cured.

Dr. Dudley remarked that the first case in which he operated was similar to the one just reported. The patient suffered so severely from shock that he was obliged to turn her upon her back, when some of the contents of the tumor entered the peritoneal cavity. At the time of the operation the pelvis was apparently perfectly healthy, but in five months the woman died of return of the sarcoma in the pelvis.

The specimen was referred to the Committee on Microscopy.

Dr. F. C. Fuller mentioned a case in which there had been a notable duration of life with malignant disease, there being a history of active recurrent cancerous disease of the pelvic organs from December last until the present time.

Dr. Dudley also presented

THE SAC OF AN OVARIAN TUMOR

which, together with the contents, weighed seventy pounds. The sac weighed eight and a half pounds. The tumor was removed from a woman fifty years of age, who was married when twenty-seven years old, and had had substantially a normal history of menstruation. Her labors had been normal, and she had not had a miscarriage. Her last pregnancy occurred sixteen years ago. She had never suffered from irritation of the bowels nor vesical symptoms. The chief, and nearly the only, symptom was constant pain, varying in severity. Her body, at the time of the operation, was lighter than the tumor, and he operated without the expectation that she would recover from the shock.

From the pubis to the umbilicus the distance measured 15 inches; from the anterior superior spinous process of the ilium to the umbilicus, 18½ inches; from the ensiform cartilage to the pubis, 30 inches; half the distance around the body, 26½ inches. The tumor was universally adherent. The woman lived five days, and died from complications.

Dr. Dudley further presented

THE OVARIES AND TUBES

removed from a woman thirty-four years of age, who was married at the age of fourteen, and had had two labors and three abortions. Her general health had been very poor, and locomotion had been difficult. There had been periodical gushes of water from the vagina. Hydro-salpinx on the left side was diagnosticated. She had gonorrhœa several years ago. The leucorrhœal discharge which she had, had never been purulent. The uterus was retroverted and bound to the pelvis, and there were extensive adhesions of the ovaries and the tubes on both sides. The operation confirmed the diagnosis, and the case was reported to illustrate how close the diagnosis might be in a case that was carefully studied.

He mentioned a case reported to the Maine Medical Association, in which the diagnosis of hydro-salpinx was based largely on the periodical occurrence of copious watery discharges from the vagina. Removal of the tubes relieved the patient entirely.

Dr. Ferguson remarked that in thirty out of sixty or seventy-five post-mortem examinations he had made in cases of salpingitis the tubes were found closed.

Dr. J. S. Thacher, by the kindness of Dr. Jacobus, was able to present an extreme case of

CONGENITAL UMBILICAL HERNIA, WITH MARKED ABSENCE OF DEVELOPMENT OF THE ANTERIOR ABDOMINAL WALL.

It was interesting on account of the size of the mass, and the obstacle which it offered to delivery.

The child was a full-term child, and its movements were said by the mother to be active till a few hours before labor-pains began.

The mother was a primipara, twenty-four years of age, and in good health. She had had two slight falls, a few weeks before, but with no apparent injury. There was no history of congenital malformations in the families of either parent.

The membranes ruptured fourteen hours before pains began, and the waters contained some fæcal matters, as they were discharged at intervals through the day. When examined, soon after the labor began, a transverse presentation was found, and protruding from the uterus, besides an arm, a peculiar mass, feeling like a portion of the amniotic sac, containing about a pint of fluid, and something like a placenta. It was found to be attached by a pedicle high up.

Podalic version was performed, and the child extracted. During version the bag ruptured. The intestines were born with the hips. The liver, also outside of the body, interfered some with the birth of the shoulders. The cord and placenta were normal.

On examination after birth, there was found an absence of a considerable portion of the anterior abdominal wall, about four inches in extent, the edges of which were continuous with the thin membrane which formed the sac mentioned. In this, and quite outside of the trunk, lay the liver, spleen, left kidney, and most of the intestines, while the stomach and uterus protruded partially. The heart was displaced downward, but inside the trunk. There was marked right lateral bending of the spine.

Dr. F. C. Fuller presented a

DERMOID CYST OF THE OVARY,

removed from a patient thirty-seven years of age, married, who came to him, last June, complaining of irritation of the bladder, which he regarded as due to mechanical pressure. There was occlusion of the vagina, which had existed during married life. There was a tumor in the right side of the pelvis, which pressed the uterus forward and to the left. He tapped it with a small needle, and obtained, thick, yellow pus. He then aspirated the sac and drew off one pint of pus, and the patient remained relieved for some time. She got into the care of another

practitioner, but finally came under Dr. Fuller's observation again, when the evidence of a pelvic abscess was obtained, which he opened into the vagina. Soon after, the symptoms led to the diagnosis of rupture of the abscess into the peritoneal cavity, and laparotomy was performed immediately. It was with very great difficulty that he succeeded in removing the pelvic contents and inserting a drainage-tube through the vagina. The patient died of exhaustion. The diagnosis of dermoid cyst was made by exclusion, and confirmed by the few hairs which protruded into the vagina when the abscess was opened.

Dr. Fuller also presented a specimen of

INTRA-CAPSULAR FRACTURE OF THE NECK OF THE FEMUR.

The patient was a woman eighty years of age, and in excellent health. She died four days after the accident, of cerebral apoplexy. The autopsy showed that there was no impaction, which was thought to be present at the time the diagnosis of intra-capsular fracture was made.

Dr. Dudley assisted Dr. Fuller in his ovarian case, and he remarked that he once had a similar one in which there was a pelvic abscess separate from the dermoid cyst. These were the only cases which he had seen where there was a simultaneous development of an ovarian tumor and a pelvic abscess.

Dr. Frank Ferguson presented a specimen of

ANEURISM OF THE THORACIC AORTA,

which was interesting chiefly on account of its size. It was removed from the body of a man fifty years of age, a native of Italy, single, an artist by profession, who was admitted into New York Hospital, into the service of Dr. George L. Peabody, on September 22, 1887. He gave no family history bearing on his case. He used alcoholic beverages moderately. Fifteen years previous to admission he had had a chancre, which was followed by an eruption. Three years ago he began to suffer from pain in the left shoulder, which gradually grew worse; a year later he began to cough, with whitish expectoration. Ten days previous to admission he began to suffer from shortness of breath, to grow hoarse, and to suffer from dysphagia. His appetite was poor; he was constipated, but his pain was his chief complaint.

On admission his temperature was 99° F.; respiration, 22; pulse, 84. He was poorly nourished; and on physical examination, all over the chest anteriorly, except at the upper part of the sternum and at the apices, the percussion-note was hyper-resonant, and over this area were heard a great many sonorous and sibilant râles. The cardiac sounds were faint, with the second aortic sound slightly accentuated. The pulse was fair in tension; the peripheral arteries were tortuous and atheromatous. There was a slight arcus senilis. In the interscapular region, to the left of the median line, there was a bulging of the thoracic wall, measuring vertically 12 inches and transversely 8 inches. Over the entire tumor was expansile pulsation and flatness, but no murmurs could be heard.

Examination of urine.—Yellowish in color; reaction alkaline; sp. gr. 1.010; albumen present in small amount. On microscopic examination, granular casts and triple phosphates were found.

While in the hospital he suffered considerable pain, which was easily controlled by morphine, and he was fairly comfortable till ten minutes before death, when he began to cough up blood and suffer intensely from dyspnœa. He died three days after admission.

Autopsy.—The left lung was bound to the thoracic wall by old adhesions, and it was also firmly connected with a large aneurismal sac, which occupied the posterior half of the left pleural cavity, above the seventh rib. This sac measured transversely 22 ctm., or 9 inches, and vertically 19 ctm., or 7½ inches. It extended 10 ctm. to the right of the median line. The third, fourth, fifth, sixth, and seventh ribs were eroded, the third and seventh partially, and the rest completely. The dorsal vertebræ corresponding to these ribs were also eroded, the fourth, fifth, and sixth most extensively. The sac communicated with the aorta by a circular opening 3 ctm. in diameter, and 4.5 ctm. below the origin of the left subclavian artery. This sac was filled with laminated fibrine and recently coagulated blood. The œsophagus and trachea were pushed forward, and to the right. The œsophagus, laid open, appeared normal. In the median line of the posterior wall of the trachea, on a level with the division into the primary bronchi, was an opening half a centimetre in diameter. Surrounding this opening the wall of the trachea was much thinner than normal, and it tapered to the thickness of tissue-paper at the edges of the opening. One centimetre from the opening two of the cartilages of the trachea were exposed, to a limited extent, through the mucous membrane of the tube. The heart was normal in size; its valves were competent, but the muscular tissue was pale. The aorta throughout was atheromatous.

Dr. Ferguson also presented a specimen of

CARCINOMA OF THE STOMACH, UNATTENDED BY GASTRIC SYMPTOMS.

A negro, aged fifty-seven, a native of the United States, married, and a caterer by occupation, was admitted into New York Hospital, into the service of Dr. G. L. Peabody, on August 30, 1887. His mother died of consumption, and he also lost a son from the same disease. He denied rheumatic and venereal trouble. He had a moderate alcoholic habit. Thirty years ago he had had malarial fever. For a period of one year, commencing eight years ago, he had had frequent pulmonary hemorrhages. For five years he had had a cough, with muco-purulent and bloody expectoration, night-sweats, afternoon fever, and he became weak and emaciated. At the expiration of five years he partially recovered his health. He had coughed up no blood for the past eight months. Eighteen months ago his feet began to swell, and he passed his urine more frequently and in larger quantities, its color being pale. He had muscæ volitantes, tinnitus aurium, and considerable headache, limited to the left side. His eyesight was impaired, and he had become short of breath, especially on exertion. Recently he had had no further pulmonary symptoms. His appetite was fair. His bowels were irregular, but he gave no other symptom referable to the digestive tract. His chief complaint was pain in his back. On admission his temperature was 97° F.; respiration, 24; pulse, 74.

Physical examination.—All over the chest, anteriorly, percussion was hyper-resonant, and expiration prolonged. Posteriorly there was flatness over both bases, with diminished voice and breathing. The heart was apparently enlarged; the first sound was markedly accentuated at the apex. The liver-area was diminished in size. The spleen-area was normal. The tension of the pulse was rather high. There was marked œdema of both legs.

Examination of urine.—Yellow; acid; sp. gr. 1.012; albumen a trace; granular casts and blood-cells found under the microscope.

Shortly after admission he became delirious, and the œdema increased. His urine was passed involuntarily; it contained granular and hyaline casts. He became comatose later, and died on September 27th. His temperature was throughout subnormal.

Autopsy.—The heart was small, and its muscular tissue brownish. The valves were normal in capacity and apparently competent. The aorta was atheromatous. There was emphysema of the right lung along its free border; in other localities it was œdematous. The left lung was intensely œdematous. The kidneys showed the lesions of chronic diffuse nephritis, and contained a great deal of fat. The stomach contained six or seven nodules, varying in size from half an inch to one inch or more in diameter. One was distinctly pedunculated, and some of them were slightly umbilicated. Micro-

scopical examination revealed that they were carcinoma. This disease had not been suspected during life.

Dr. Boldt referred to a case in which the patient died of consumption. The only symptom referable to the stomach during life was some pain after eating, but the autopsy revealed carcinoma of that organ.

The Society then went into executive session.

Correspondence.

"CHOLERA IS ALWAYS STOPPED BY COLD WEATHER, AND AN EPIDEMIC HERE NOW WOULD BE IMPOSSIBLE."—The Medical Record, p. 598.

To the Editor of The Medical Record.

Sir: In your issue of November 5th I notice an editorial on "Cholera and Quarantine," in which occurs the following remark: "The attempt to frighten the public into fear of cholera at this time, however, is simply part of the newspaper methods of the day. Cholera is always stopped by cold weather, and an epidemic here now would be impossible."

That such a statement should be found in the editorial columns of a leading medical journal, I confess, fills me with surprise, as everyone who has reviewed, even slightly, the history of the various cholera epidemics knows that, unlike some other diseases, cholera is one of those scourges whose march is not stopped by heat or cold, high or low altitude, dryness or dampness, or any other condition of the weather.

In 1830 the cholera appeared in Moscow in the month of October, and continued its ravages until the end of December, in spite of the severities of a Russian winter, and caused the death of 8,130 persons out of a population of 250,000, or about 1 in 30. From Moscow it went north to Yarasy, thence to Rybinsk, sixty leagues north of Moscow, where it appeared on March 19, 1831, in spite of the ice and snow which covered the ground.

In October, 1831, the cholera appeared in Great Britain, and continued there until March, 1832, doing most of its destruction in December. About one-third of the people affected died.

On the 27th of March, 1832, the disease appeared in Paris, and the mortality was so frightful that 861 people died in ten days.

In 1848 the emigrant ship New York left Havre on the 9th of November, having no sickness on board and no cholera being then in Havre. During the voyage the weather became bitterly cold. There were some German emigrants on board, from a town where cholera had prevailed, who had a trunk which had belonged to a man who had died of cholera. They opened the trunk, took out the clothing, and wore it. On November 22d a child died of cholera, and seven persons in all succumbed to it before reaching New York Harbor.

They were strictly quarantined and the disease limited to those who died on Staten Island in the Quarantine.

About this same time another vessel from Havre, bound for New Orleans, developed the cholera on the twenty-seventh day out, and owing to imperfect quarantine regulations the disease spread rapidly through the town soon after the arrival of the vessel, there being then no other cases in the United States except those in the Quarantine on Staten Island. From New Orleans the disease travelled to Memphis, appearing there toward the end of December, and at St. Louis in the first week of January, 1849. Toward March several places in the Upper Mississippi Valley were affected, and then gradually the disease moved east through Chicago, which it reached in May, to New York, which became infected then, *and not till then*, although the disease had been imported to the city six months previously, but had not been allowed to land, and the city in this way kept free from infection until the cholera effected a flank movement, by way of New Orleans, and attacked her in the rear, having made its progress in spite of the winter, and having attacked the cities through which it passed in the cold weather.

These facts in regard to the prevalence of cholera in spite of cold, and the well-known futility of a quarantine on land, make any attempt to lull the medical profession into a false sense of security fraught with great danger to the country, and I have, therefore, wished to call attention to the fact that cholera is *not* stopped by cold, and that to be quarantined effectively it must be arrested in our ports, which can only be done by having a general quarantine under the direction of the Federal Government.

Yours respectfully,

Reginald H. Sayre.

285 Fifth Avenue, November 7, 1887.

[Cholera has never prevailed in New York City in the winter-time, and rarely in any northern latitudes save under very peculiar and exceptional circumstances. We gave what we believe to be the rule in regard to cold weather, and had in mind the statement of Dr. Harold C. Ernst, who has written an authoritative article on cholera in the "Reference Handbook of the Medical Sciences." He says: "The progress of an epidemic is invariably arrested by cold—the winter season having always stopped those of which we have any record."

The old idea that cholera wintered over frequently is now almost exploded. In Russia the peasants' huts and village houses have only one window, which is always closed in winter, and no door opening directly to the outer air. The outer door opens upon a long hall, at the other extreme end of which is an inner door which opens into the large living-room, where several generations are huddled together at night, viz., grandparents and great-grandparents and their families, sons and daughters and theirs, and so on to the extent of three or four large families, all of which are heated up by the huge, hot Russian stove. In winter the rice-water discharges are apt to be thrown out upon the snow, which is soon after collected and put in the tea-kettle or soup-pot. The larger Russian houses are tremendously overheated, more so than our furnace-heated houses. At the last visit of the Grand Duke Alexis here, he and all his staff complained bitterly of the coldness of New York houses.

Cholera has frequently been imported into warm New Orleans in the winter-time, notably in 1873, when it commenced in February. But it did not winter over in the United States that year or, notably, any other year. But constant importations into New Orleans, almost every month of the year during the California gold-fever times, sent much cholera to St. Louis and Chicago, and other western places, almost every month in the year, so that it seemed to winter over; but, in fact, was kept alive by almost incessant new importations.

Our esteemed correspondent has opened up a very interesting question, and we are glad that he has called attention to it, so that it may be properly discussed.—Ed.]

THE GLEDITSCHINE INVESTIGATION AND RESERVED RIGHTS.

To the Editor of The Medical Record.

Sir: In a note from Dr. J. Herbert Claiborne, Jr., published in The Medical Record of this date, I find it stated that you and I have consented to nominate a chemist and a botanist to superintend an attempt on the part of Mr. Goodman and Dr. Seward to extract an alkaloid from the *Gleditschia triacanthos*, together with this statement, "the condition to be imposed is that the chemist, on his word as his bond, is not to divulge the method of procedure of obtaining the substance."

I took pleasure in acceding to Dr. Claiborne's request that I should act with you in the capacity in question, but I did not suppose that any such condition was to be

attached to the arrangement. Dr. Claiborne said something about a desire on the part of Mr. Goodman and Dr. Seward that their process should be kept a secret, but I told him that that was impossible, and I thought that he agreed with me. Had I supposed that such a condition was seriously intended to be made a part of the plan of procedure, I should have declined to have any connection with it, for it seemed to me that it would be unsatisfactory to the profession and an indignity put upon the chemist and the botanist who were expected to perform a service in the interest of science.

FRANK P. FOSTER.

NEW YORK, November 5, 1887.

[To a certain extent Dr. Foster is right, and we agree with him. We regret to lose his valuable assistance. THE RECORD will, however, investigate the matter on its own account, and, we trust, in the proper way.—ED.]

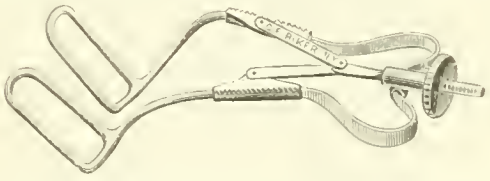
New Instruments.

A NASAL SPECULUM.

BY W. J. SWIFT, M.D.,

NEW YORK.

I WISH to call attention to a nasal speculum which I have used for some time in my clinic at the Metropolitan Throat Hospital, as well as in my office practice, and which, it appears to me, is not so well known as it deserves to be. The cut shows the principle upon which



it is constructed, being, namely, a combination of Fraenkel's nasal speculum and Noyes' eye speculum—the spring at one extremity, acting to keep the blades open, and the nut serving to regulate the extent of their separation. It is light, self-retaining, and easily adjusted to any nostril, and is decidedly the most useful nasal speculum with which I am acquainted.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 30 to November 5, 1887.

BYRNE, CHARLES B., Captain and Assistant Surgeon. Ordered for temporary duty at Fort McHenry, Md. S. O. 231, Division of the Atlantic, October 28, 1887.

MUNN, CURTIS E., Captain and Assistant Surgeon. Relieved from duty at Fort Canby, Wash. Terr., and ordered for duty as Post Surgeon at Fort Klamath, Ore. S. O. 251, A. G. O., October 28, 1887.

ADAIR, G. W., Captain and Assistant Surgeon. The leave of absence for seven days, granted on the 27th inst. by the commanding officer, Fort Brady, Mich., is extended twenty-three days. S. O. 231, Division of the Atlantic, October 28, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending November 5, 1887.

FITZSIMMONS, P., Surgeon. Ordered to the United States Ship Marion.

ATLEE, L. W., Assistant Surgeon. Ordered to the United States Ship Marion.

BATES, N. L., Medical Inspector. Ordered to the United States Ship Trenton.

BEYER, HENRY G., Passed Assistant Surgeon. Ordered to the United States Ship Trenton.

WHITE, STEPHEN S., Assistant Surgeon. Ordered to the United States Ship Trenton.

RIXEY, P. M., Passed Assistant Surgeon. Detached from the United States Ship Trenton and wait orders.

ASHBRIDGE, RICHARD, Passed Assistant Surgeon. Ordered to the United States Receiving Ship St. Louis.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 5, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	25	4
Scarlet fever	85	9
Cerebro-spinal meningitis	3	3
Measles	53	3
Diphtheria	122	32
Small-pox	2	0
Yellow fever	0	0
Cholera	0	0

ACUTE INTESTINAL OBSTRUCTION.—Dr. George J. Charlesworth, of Plum Creek, Neb., criticises the treatment adopted in a case of intestinal obstruction reported by Dr. Perry in a recent number of THE MEDICAL RECORD. He says that the administration of active cathartics in acute intestinal obstruction is a procedure condemned by the latest authorities, and he warns all practitioners against it.

INDIGO IN AMENORRHŒA.—Dr. J. W. Cutler, of Platteville, Wis., referring to an article in THE MEDICAL RECORD of July 9, 1887, on "Indigo as an Emmenagogue," writes that he has used the drug for that purpose for two years or more with excellent results. He learned of this property of indigo in the pages of *The Dispensatory*.

INDIGO FOR RATTLESNAKE-BITE.—A physician writes in the *Medical and Surgical Reporter*: "The Hon. George Opdyke, mayor of the city of New York during the late war, told me that wet pulverized indigo is a sure and certain cure for the bite of this reptile. I mentioned this to a lady about to start to Florida, in February last, who had occasion to use it. Their colored servant was bitten above the ankle. He tied a bandage tightly above the ankle and kept on with his work. In the afternoon the foot and leg, to the bandage, were swollen dreadfully. Indigo was applied as a poultice, and the man recovered without other treatment in twenty-four hours."

DOUBLE URETHRA IN THE MALE.—At a recent meeting of the Society of Physicians of Styria, Dr. Lipp showed a man with a double urethra. The patient, aged twenty-five, had been admitted into the hospital suffering with acute gonorrhœa, and on examination a second opening, which was surrounded by a limbus, and through which one could introduce the sound into a canal lined with mucous membrane, was found to be present over the opening of the urethra near the corona glandis. The canal extended as far as the posterior part of the symphysis.

Original Articles.

SOME CONSIDERATIONS ON LITHÆMIA AND ALLIED DISORDERS, WITH ILLUSTRATIVE CASES.[1]

BY THOMAS E. SATTERTHWAITE, M.D.,

NEW YORK CITY.

FROM the present stand-point of our progress in physiological chemistry the word *lithæmia* is a very useful one. Originating, as it did, with Murchison,[2] who pointed out a definite train of clinical phenomena to which the name was applicable, it has been extensively utilized of late years in the United States; while some of our ablest clinicians, such as Drs. Da Costa and Bartholow, have adopted, in great measure, Murchison's views as to the natural history of the disease in its various manifestations.

It is but just, however, to state, at this point, that the late Dr. Austin Flint[3] had already proposed the word *uricæmia* for morbid conditions of a similar or allied nature; but the matter did not at first attract general interest, so that it was reserved for Murchison to fasten the word lithæmia to a special group of symptoms, and he did it in so masterly a manner that not only were his views heartily commended, but the word *lithæmia*, which he proposed, was grafted upon our medical terminology. But, as will further appear, an acknowledgment of Murchison's position with regard to lithæmia seriously affected certain doctrines that were long held on the subjects of oxaluria[4] and phosphaturia,[5] and which, even now, have their advocates. Before passing, therefore, to the practical aspects of lithæmia, it will be necessary to note the relations of these several conditions.

But, in so doing, it will be important, and, indeed, essential, to take a hasty glance at some elementary facts of physiological chemistry, and particularly those that refer to the production of urea, uric acid, and the urates; oxalic acid and the oxalates; phosphoric acid and the phosphates—for, as appears from a brief survey of these topics in our modern text-books, these several substances have, all of them, close relations with one another, whether they are in or out of the body.

To begin, then, with the first mentioned, it may be stated, as a matter of common acceptance, that urea is the ultimate product of the metabolism (*i.e.*, conversion) of the proteid (albuminous or nitrogeneous substances) ingested as food; and the chemical formula of urea $(CONH_2)_2$, showing, as it does, a combination of carbonic acid, ammonia, and water, indicates its nitrogeneous character. But physiologists tell us that while it is a derivative of animal tissue-waste, it is often a remote product, and through the medium of such substances as zanthin, hypozanthin, etc., which are then known under the name of intermediate products in the destructive metamorphosis which the body is constantly undergoing; and though, as experiments have shown, the amount of urea elaborated in the system corresponds, in great measure, with the amount of destructive change, as in fevers, still, as more or less change is constantly occurring under normal conditions, it follows that the occurrence of urea among the habitual excretions should be constantly expected, of which occurrence we have abundant proof.

But though the two classes of agencies just mentioned are constantly operating and are of prime importance, there are still others at work; and yet, if the two first mentioned are in active operation at the same time, urea may be produced in enormous quantities. Such a concurrence is observed often in glycosuria, where there is both an increase in the amount of nitrogeneous food ingested and an excessive waste of tissue. The urine in such cases may contain treble its normal constituent quantity of urea, and the normal average of five hundred grains may be augmented to three ounces.

Now, it has long been a question among physiologists whether or not the liver is the organ that elaborates urea; but though it can fairly be said that we have evidence to show that urea *can* be formed in many parts of the system, actual experiment has demonstrated conclusively that urea *may* be formed in the liver from the carbonate of ammonia *in a direct manner;* while apart from this last-named fact, other experiments, as upon birds fed with leucin, tyrosin, glycin, asparagin, and aspartic acid, have shown such an increase in the urea of the urine as to lead to the supposition that it is formed in the liver, where the above *amido acids*, as they have been called, developed through the tryptic action of the pancreatic ferment, are carried by the portal blood during intestinal digestion; and yet it is still within the limits of possibility that urea may also be formed synthetically from the nitrogen of the animal fluids, through chemical union with these same amido-acids.

But the proof that urea is produced by hepatic action is further sustained by such unquestionable evidence as its increase in the tissue of the liver after electrical stimulation, and a decrease in the normal amount when the liver has been the seat of destructive changes, such as are known to occur in acute atrophy or fatty degeneration.

The subject of *uric acid* next invites our attention, and its clinical formula, $C_5N_4H_4O_3$, demonstrates the close relationship it holds to urea. But uric acid is a highly insoluble substance, and is rarely found in the body. Certainly it is *not* found in the diseases under their normal condition, except during infantile life, in the first few days of separate existence; and then the deposits which occur, and which have been so frequently noted in the pyramids of the kidney, are probably an exhibition of the circumstance that the digestive functions of the new-born have not yet found themselves fully competent to cope with the new substances that have been ingested for the independent life of the individual. But it will be noticed that these deposits rapidly disappear, so soon as the new conditions have been satisfactorily established, and we may properly connect the disappearance of the deposit with the establishment of an equilibrium based upon the new conditions of the individual with respect to its digestive functions.

There is one disease only, so far as is known, in which uric acid exists alone—*i.e.*, uncombined—in the body. In this single disease, leucocythæmia, it is found in the spleen, though of this matter I cannot speak from individual experience, having, in fact, never seen it in such spleens as have come under my notice. But the urates,

[1] Read at the Seventh Annual Meeting of the Ontario Medical Association, held at Toronto on June 8 and 9, 1887.

such, for example, as those of ammonia, soda, potash, and lime, all which are highly soluble, occur frequently in the fluids of the body.

There is, further, a well-sustained theory that uric acid is formed from many of the substances that are themselves derived from the intestinal digestion of albuminous matters, such, for example, as guanine and the like; uric acid may also be derived from urea, as the latter is derivable from the former. It is not unlikely, however, that both of them may be developed in various parts of the body; though from the considerations above given it seems most probable that the liver is the point from which uric acid chiefly takes its origin, and the ingestion of albuminous food predisposes greatly to its production. But by far the larger portion of the nitrogeneous or albuminous foods ingested is excreted as *urea*, as residue only going to form uric acid, or creatinine or hippuric acid.

Now, in reference to oxalic acid and the oxalates of lime, which next require our attention, it must be remembered that many vegetable substances taken as food contain oxalic acid to a more or less degree. Thus, rhubarb possesses it in large amount, while asparagus, cauliflower, spinach, apples, tomatoes, and even grapes have it in more or less quantity (Fagge). And some medicines, such as gentian, also contain it. On the other hand, oxalic acid is readily produced within the system,[1] and the experiments of v. Wohler and Frerichs sustain this statement. It is further maintained that oxaluria may be occasioned by the drinking of champagne, or, in fact, any carbonated water, as an oxalate may be formed in the animal system through the agency of any carbonate. For a similar reason the inordinate use of sugar might lead to oxaluria. But it is hardly necessary to multiply instances to prove that oxalic acid may be formed from other normal products of tissue-change—a notable example of this fact, however, has been adduced (Weber[2]) to show that guano, which is largely made up of the urate of ammonia, may be spontaneously converted into the oxalate of ammonia in the ship's hold; and it can be shown, as Owen Rees[3] first pointed out, that uric acid is readily converted into oxalic acid and urea by the addition of water.

Such varied evidence would therefore demonstrate that oxalic acid may simply be formed during the decomposition of uric acid or urea, and it follows naturally that the clinical phenomena associated with the two conditions, oxaluria and lithæmia, have a close relation.

As, therefore, at the present day, we come to understand these fundamental postulates of physiological chemistry, the more do we recede from the stand-point taken by those who have sought to establish oxaluria as a distinct disease.

Nor, apart from this medical aspect of the so-called oxalate-of-lime diathesis, is there anything markedly distinctive in its surgical relations? It cannot be said that there is anything peculiar in the system by which an oxalic calculus is formed rather than a phosphatic, though it is true an oxalate of lime-stone possesses physical qualities, such as roughness and hardness, which, on the one hand, cause it to do unusual violence to adjacent parts, and, on the other, make it more difficult for the surgeon to remove. From a prophylactic view, it matters not to the surgeon whether it be one or the other.

What, now, is phosphaturia?

It is generally conceded that the phosphoric acid of the urine is either obtained from food or from the oxidization of the waste products of the body. But phosphoric acid does not occur uncombined; for though about fifty grains is daily excreted, it is always in combination with such bases as potash, soda, magnesia, lime, or ammonia. These salts are held in solution by the acid phosphates of soda. If, however, the acid phosphates be diminished in quantity, the earthy phosphates may be deposited; but the mere fact of such deposition does not indicate that they are necessarily in excess, as readily occurs to anyone who is conversant with the physiology of the urine. Determination of an excess or a deficiency of the phosphates can be computed by quantitative analysis only. And yet I will venture to say that this matter is of little consequence, because most careful study has so far failed to show that an excess of the phosphates demonstrates any peculiar condition of the system, or, in fact, that a diminution in the amount of phosphates has any important signification.

So far as these deposits are concerned, they are either of the triple-phosphate variety or of the phosphate of lime, and are natural to any urine when it becomes alkaline.

And the reason that these deposits of the phosphate of lime cannot yet be regarded as having any definite clinical significance is because heretofore they have been found in diseases of so different a character as to indicate nothing common to the several cases. Prout's phosphatic diathesis was based upon his recognition of the ammonic phosphate of magnesia found in ammoniacal or decomposing urine, and Golding Bird described a train of symptoms that are common to both his so-called oxaluria and lithæmia—viz., nervous prostration, dyspepsia, and melancholia, or hypochondriasis.

There are but two points to be remembered in this connection—viz., that the urine becomes alkaline either (1) from the fixed alkali, soda or potash, or (2) from the volatile alkali, ammonia. When the latter condition prevails, the phosphates are simply due to the decomposition of urea; when the former prevails, or even is frequently present, the patient usually suffers from dyspepsia, anæmia, or debility, but the presence of the phosphates does not indicate any precise disease. I do not mean to state now that we may not, at some future time, find some relation between true phosphaturia and a special train of clinical phenomena, but I state that, in my opinion, no such connection has yet been shown; and with this view of the case we are better prepared to study the clinical aspect of lithæmia, which is conveniently divided into three types: 1. The hepatic. 2. The neurasthenic. 3. The articular (gout).

But before coming to this matter it may be well to premise that there is a great difference between the occurrence of uric acid or the urates in solution or as a deposit. For we must not think that an excess of either one or the other, as a urinary sediment, indicates an excess of either in the blood or tissues. Their deposition in the urine is a matter that depends largely upon the density of the liquid, its acidity, and the temperature of the liquid; and, in fact, the density of the urine may, in acid urine and on a cold day, determine whether the uric acid or the urates are deposited. Thus, with an average specific gravity of 1.021, and the other conditions just named, we may expect a deposition of uric acid, while with a specific gravity of 1.027 we may look for urates (Roberts). The quantitative estimation of uric acid, which is of most importance and can alone determine whether there is an excess or a diminution, should be done by precipitation with hydrochloric acid in the usual manner, and is naturally a chemical procedure of some difficulty.

Hepatic lithæmia is well described by Murchison.[1] He says: "When oxidization is imperfectly performed in the liver, there is a production of the insoluble lithic acid and lithates instead of urea, which is the soluble product from the last stage of the oxidization of nitrogeneous matter. Again, when more food is taken into the blood than is necessary for the nutrition of the tissues, the excess is thrown off by the kidneys, lungs, and skin, in the form of urea, carbonic acid, and water, or in the imperfectly oxidized forms of lithic acid and oxalic acid.

[1] Landois and Stirling, ii., p. 534.
[2] Weber: Wood's Reference Handbook, iv., p. 509.
[3] Rees: Croonian Lectures, 1856.

[1] Murchison: On the Diseases of the Liver, p. 626. 1885.

"Under these circumstances an excess of work is thrown upon the liver and other glandular organs, and one result is that a quantity of albumen, instead of being converted into urea, is discharged by the kidneys in the form of uric acid or its salts. But what, in most persons is an occasional result of an extraordinary cause is in some almost of daily occurrence, either from the food being always excessive in amount or unduly stimulating, or from some innate (often hereditary) or acquired defective power in the digestive organs, in virtue of which their normal functions are liable to be deranged by the most ordinary articles of diet. This functional derangement of the liver in certain individuals, particularly the offspring of gouty parents, may manifest itself by various symptoms of indigestion, by disturbances of the circulation and of other physiological functions, but especially by deposits of lithic acid, lithates, and pigments in the urine."

Now the symptoms in these cases, as further described by Murchison, are about the same as those that have been said by Prout and Golding Bird to belong to oxaluria—viz., increased desire to pass water, flatulence and other dyspeptic symptoms, intermittent pulse and palpitation, torpor of bowels, lassitude and languor, even melancholia.

Let us next briefly consider some of the theories of gout which, being characterized by a deposit of the urate of soda in the joints, must be included, pathologically, under the general topic of lithæmia. It is proper, therefore, to consider them here:

1. There is the *neurotic theory*. This carries us back to the time of Cullen, though it has not been in want of able defenders since his time (Paget). It is based upon the fact that certain persons, independent of their mode of life, whether sedentary or otherwise, whether they enjoy the pleasures of good-living, alcoholics, etc., are still sufferers from acute attacks of gout, while, conversely, persons may freely indulge and still not suffer in the least degree. Believers in the neurotic theory of lithæmia also point to the prevalence of mental disturbances, or severe shocks to the nervous system, as provocative of an attack; while, too, again, in a neurotic family, attacks of gout will occur in one individual, and certain nervous affections in another. And, in addition, it is suggested, by those who adhere to the view, that joint-affections are both common to gout and, again, nervous diseases, as, for example, locomotor ataxia, with its arthropathies.

2. No mention can be made of the pathology of lithæmia without reference to Garrod,[1] who, in 1848, showed that the blood of gouty persons contained the urate of soda in large quantities. According to Garrod, in gout or lithæmia there is an excess of uric acid in the blood, due to either an actively increased production or a diminished elimination, while at the same time the blood is unduly alkaline, which latter condition causes the precipitation of uric acid under the form of the insoluble urate of soda. The causes of such an increase in uric acid may be due, on the one hand, to an excessive indulgence in nitrogeneous food, leading to inadequate conversion (metabolism), or, again, this insufficient elimination may be due to another set of causes, such as a deprivation of oxygen, or defective action of the kidneys. And, in particular, he held the view that the renal function of excreting uric acid might be temporarily suspended, and that in such instances the joints would receive the acid under the form of the urates which otherwise should have left the body by the avenues of the kidneys.

And Garrod claimed that the two phenomena followed one another consecutively. Thus, when an accumulation of the urates had occurred in the blood, they first gave rise to gastric and neurotic disturbances, and finally, as a second stage, deposits took place in the joints during an acute attack of gout.

Now, many of the facts thus stated have a fair degree of evidence in their favor, but the diminished alkalinity of the blood, of which he speaks so freely, is not a matter of ready proof.

3. Finally, the peculiar views of Ebstein merit attention, as he, next to Garrod, has been the most diligent student of lithæmic pathology. According to this author[1] uric acid is produced in many parts of the body, but it is the muscles and bones especially that form it, the depositions in joints being due to the sluggish circulation there. Gout, according to Ebstein, is usually inherited, though it may remain in a latent condition for years. In the pains and soreness of the muscles he sees the origin of uric acid, which he supposes to be formed from kreatin, sarkin, and zanthin, all of which are found in muscle and are closely allied to uric acid, so far as their chemical constitution is concerned. But of the actual finding of uric acid in muscle he gives no proof.

It will thus be seen that of the theories propounded no one is established upon a perfectly sound basis, although each one has some elements of truth in its favor.

For we may say of the neurotic theory, that as the operations of glandular organs are under the control of the nerves, defective nerve-action will prevent proper glandular activity, and this state of things is plainly seen in diabetes mellitus; and it may further be necessary for the deposit of the urates in gout that defective innervation of the joints may precede the attack. At any rate, it will be granted that a serious shock to the nervous system often determines the malady. And so of Garrod's theory, it having been proved that urea can be formed in the liver, and that urea is convertible into uric acid and *vice versa*, it follows that the conditions which dispose to the one may dispose to the other; and our clinical experience demonstrates this fact beyond cavil, so far as relates to the excessive use of nitrogeneous food and spirituous liquors. But, finally, an acceptance of these two theories does not debar us from adopting Ebstein's views, so far as they indicate that uric acid may be formed in various parts of the body apart from glandular organs. In fact, if urea can be formed almost anywhere in the body, it is credible that uric acid may also be formed in a similar way under analogous circumstances.

Let us note with more detail the symptoms of these three varieties of lithæmia.

1. The hepatic form (hepatic dyspepsia): This variety of lithæmia introduces us at once to the sphere of the digestive functions, in which portal and hepatic congestions play important rôles. Prominent among the symptoms are those of gastric catarrh, distress in the epigastric regions, especially after eating, with drowsiness; acid eructations, a furred tongue, and sluggish bowels. Palpitation will occur if the stomach be at any time dilated.

2. In the neurotic form the patient is apt to suffer from neuralgia, frontal headache, tinnitus aurium, a sense of weariness in the limbs, some form of mental aberration, perhaps, such as melancholy or hypochondriasis. Sometimes there are vertigo, muscular cramps, spinal irritations, vaso-motor disturbances, delusions, and, perhaps, epileptiform symptoms.

3. In gout we have as a substratum either of the above forms, while there is in the individual a tendency, that is usually, if not always, inherited, to deposition in joints, possibly induced, as Garrod thinks, by the alkalinity of the blood. Understanding, as we now do, in a measure at least, the physiology of the production of uric acid and the urates, the plan of treatment is comparatively plain, as also the natural consequences to the individual from a persistence in those modes of life that lead to the excessive formation of these substances.

Diagnosis.—1. In the hepatic form a diagnosis rests upon the regular occurrence of uric acid in the urine, and especially, before the usual acid fermentation takes place, upon the deep color of the urine, and its high

[1] The Blood and Urine in Gout, Rheumatism, and Bright's Disease.

[1] Ueber die Natur u. Behandlung der Gicht. 1882.

specific gravity when unaffected by remedies; and by the regular symptoms of hepatic congestion, with its concurrent phenomena as already described.

2. In the neurotic form we are only called upon to differentiate from other organic or functional nervous diseases when the regular occurrence of uric acid in a urine, before the period already mentioned, will indicate the source of the disturbance.

3. In gout the peculiar attacks, affecting, as they do, usually the larger joints of the toes, preceded by irregular cramps and spasms having a short but violent exacerbation, in which the urine is notably free from uric acid, and followed by sudden and entire relief, while the urine is quickly loaded with uric acid, *indicate* with sufficient clearness that the affection is gout and nothing else.

Treatment.—Though in many cases it will be found all-sufficient to diminish the amount of nitrogeneous food, this is not always the case; for if too much dependence be placed upon the carbo-hydrates, the mucus of the gastro-intestinal tract may set up acetic fermentation and carbonic acid will be produced, and there will be that undue pressure, as the result of gaseous accumulation, which leads to neurotic disturbances, and so, indirectly, to faulty conversion of the proteid substances of the intestinal digestion. A mixed diet is therefore to be given, and care is to be taken that such substances only be digested as are thoroughly digestible. For this reason individual idiosyncrasies must be duly considered.

In lithæmia it is most essential that the bowels be freely moved, and laxative waters are most desirable for several reasons: 1, They promote the oxidization of proteid substances; 2, they cause the kidneys to do their part in elimination; and 3, they promote intestinal action. To be recommended are our own Congress waters, the Hathorn, and the foreign Pullna and Friedrichshall or Carlsbad, which owe their virtues mainly to the sulphate of soda or the sulphate of magnesia, or to both in combination. If, in addition to this line of treatment, the patient be compelled to take active out-of-door life, and be restricted entirely in the use of alcoholic stimulants, a favorable prognosis may be entertained. But while such a course of treatment is adapted for a certain class of individuals, notably those of full habit, we meet in this country with another which exhibits plain indications of neurasthenia. In this neurotic class, and they are the most common by far, the principles of treatment are those that apply to neurotic persons generally. Rest of mind and body should be enforced, and their dyspepsias should be treated, not only by a careful avoidance of substances that cause gastric irritation, but the flagging appetite should be sustained by suitable digestive ferments, such as pepsine or pancreatine, with an aromatic. And, in addition, women may take with advantage some form of tonic, and have quinine in small doses combined with a little strychnia. If stimulants be used, a little brandy or whiskey, well diluted, or a glass or two of good Hungarian red wine at meal-time. It is always well in such cases also to drink freely of carbonated waters, such as are now common all over the country. They not only produce increased oxydization, but, passing freely through the kidneys, wash or "flush" them out.

The salts of potash and lithia are also most useful, because they form soluble compounds in the urine and promote its flow. The Spring No. 2 of the Buffalo Lithia Company, in Virginia, is to be recommended in this regard, but there are many others perhaps equally useful. Such waters should be taken freely during the so-called alkaline tide, when the alkalinity of the blood is at its height. Liquor potassæ, Rochelle salts, and the citrate of lithia are also excellent remedies. Often it is necessary to combine with them some cholagogue, and I have more confidence in podophyllin than in any other one drug.

The following are illustrative cases:

Case I. *The hepatic type.*—C. P——, aged fifty-seven; New Jersey; book-keeper. The patient does not remember when he first saw gravel in his urine, but it was some years before. He has a fulness in the region of the stomach, and a pain low down in the back. During the previous day had had general depression. Once passed a small body, which proved, on examination (by me), to be composed of uric acid. Traces his trouble to abuse of alcoholic and, especially, of malt liquors. Is free from trouble when he observes a rigid dietary of milk and vegetables, without meat, and takes alkaline waters, such as the citrate of potash with Bethesda water. Is a man of full habit.

Case II. *The asthenic or neurotic type.*—J. K——, aged thirty-nine; a native of Ireland. Came to my clinic at the Post-Graduate Medical School on March 31, 1884, complaining of dyspepsia and headache. He also had hemorrhoids. Two weeks previously he had been taken with pain in the back. Appetite fair; some jaundice; intestinal pain; dyspnœa. The patient was immediately put upon the subnitrate of bismuth, five grains, with pepsine (scale), ten grains, three times a day, and relief followed.

Subsequently he returned, complaining of a recurrence of the symptoms, and he was again relieved by the use of dilute nitro-muriatic acid in minute doses, combined with pepsine and an aromatic.

Case III. *Neurasthenic type.*—E. H——, a clerk, aged thirty, consulted me at my clinic on April 5, 1887. He stated that for twelve to thirteen months he had suffered from dizziness and intermitting pain in the head, and dull aching in the lumbar region. He also frequently felt some danger impending. Appetite variable; bowels constipated; symptoms of intestinal indigestion; urine high-colored, specific gravity 1.028, strongly acid, no albumen, but an abundant deposit of uric acid. It was further found that he was very irritable and had hallucinations. He was immediately placed upon Sir William Roberts' alkaline mixture, and he was given thirty grains of the citrate of potash every four hours, to which was added, separately, strychnia in minute doses. On April 19th he was found to be much improved, free from hallucinations, and he continued improving under the same treatment, receiving, in addition, the following:

℞. Ext. nucis vom ..... gr. vj.
Ext. taraxaci,
Pulv. fel. bovis .....āā 3 j.
M. Div. in pil. No. xxx. Sig.: One before meals.

And upon May 5, 1887, he reported ready again to return to his former occupation.

Case IV. *Lithæmia, complicated by renal calculi; treatment by solvents, etc.*—On January 1, 1886, Mr. T. S—— consulted me, and gave me the following history: On February 1, 1885, while engaged in his office he was seized with a violent pain, which ran from the region of the left kidney to the bladder, so that he was obliged to take morphia to get relief. On the following day he experienced another attack, and blood was passed per urethram. During the summer, while in Great Britain, he consulted several eminent physicians who were authorities on gout and allied diseases, and one London practitioner told him that a stone was forming in the left kidney. He was put upon the citrate of potash and the citrate of lithia and strychnia, though the doses of the former were small, and probably not sufficient to render the urine alkaline. After returning to New York he consulted several of our best practitioners and a surgeon of excellent repute. His troubles, as then described, were: Constant pain in the left side; amount of water passed daily, seven pints; appetite good; mouth a little dry; drinks no more of liquids than other people; has had malarial intermittent fever. Examination of water showed absence of sugar and albumen.

Mr. S—— was immediately put upon Roberts' antilithic treatment, which consists in the administration of the citrate of potash in forty-grain doses every four hours.

On January 29th the urinary record showed as follows: Amount of water, five pints; specific gravity, 1.028; reaction alkaline; pus and epithelium present in small quantities; amorphous urates abundant.

On February 1st the urine was again acid, but faintly so, and the pain had already begun to diminish. The diet was now restricted to fish, chicken, and game, beef in small quantities, but pork, veal, and under done meat were excluded. Saccharine and farinaceous food was denied him. The urine still remaining acid, the citrate of potash was now given in thirty-grain doses every two hours. The pain was now referred mostly to a point posterior and internal to the left anterior superior spine, and in a less degree to the region of the kidney, over which there was an area of tenderness which would correspond to an enlarged spleen, having a transverse diameter of ten to twelve inches, special points of tenderness being referred to the intercostal nerves of the left twelfth rib.

On February 2d the patient passed something like blue sand, probably the urates or uric acid tinged blue by indican, as Roberts once observed in the ammoniacal urine of cystitis.

On February 4th Mr. S—— could turn about without so much inconvenience as formerly, and the points of tenderness were confined to the region of the kidney and ureter. He was now put upon the Buffalo lithia-water from Spring No. 2, as I had favorable views in reference to this spring in diseases of a lithæmic character. The decidedly alkaline nature of the water is due to the carbonate of potash and lithia, and as an alkaline water it is, for this reason, preferable to Vichy water, which owes its alkalinity chiefly to the carbonate of soda. It is also somewhat diuretic. And in addition to the dietary, butter in small quantities was allowed, and skimmed milk three times a day. Mr. S—— was still weak; and as the alkaline treatment was pushed, it was found necessary to put him upon moderate doses of strychnia and the sulphate of quinine, with occasional doses of podophyllin and other hepatics to stimulate the liver moderately.

Mr. S—— continued to improve slowly but steadily until in the early part of March, 1886, when he had several short attacks of severe pain, similar to, though not so severe as those experienced in February of 1885. The specific gravity, however, still continued very high, and on March 16th was 1.033, alkaline, and contained a moderate amount of pus, but no albumen.

On March 24th a positive diminution in quantity began, and now for the first time it was reduced to four pints; and though diminished in amount, the specific gravity also fell to 1.028. Reaction amphoteric; a moderate amount of lime oxalate. The pain was now located deep behind the anterior superior spine.

On April 13, 1886, the amount of urine had fallen to three pints. The patient was now able to travel, and was making a visit to Chicago. During this time he had given up the Buffalo lithia-water and was put upon the lithiated hydrangea made by the Lambert Pharmacal Company, of St. Louis. The action of this new medicine was found prompt and satisfactory; for, though given in drachm-doses only three times daily, the heavy uric-acid, "cayenne-pepper" deposits speedily disappeared. Each drachm is said to represent thirty grains of fresh hydrangea and three grains of the binzo-lithiate of lithia. Under this treatment, also, the urine diminished further in specific gravity, so that during April of 1886 it varied from 1.020 to 1.036, but the pain in the back still continued. As the spring was now advanced, and fresh vegetables were easily obtained, the amount of animal food formerly allowed was diminished and a more liberal diet of vegetables permitted, with a slight admixture of the saccharines.

On April 23d Mr. S—— was given the forty grains of tartrate of potash in lithia-water three times a day. Under this treatment the urine was not strongly alkalinized, and the specific gravity fell to 1.024½.

On May 10, 1886, the warm days of this season becoming too relaxing, the patient was sent to the country, where he could enjoy out-door sports in a cooler atmosphere. The change was favorable. The urine now contained the oxalate of lime; alkaline most of the time; the specific gravity fell as low as 1.022, and it averaged little, if any, more than the normal amount (forty-eight to fifty-four ounces per diem). Owing to the pus being still in the urine, and its probable origin in the genito urinary tract above the bladder, it was thought best to increase the flow of urine artificially, which was done by liberal amounts of the carbonated Clysmic water from the springs at Waukesha.

On June 7, 1886, the specific gravity had fallen to 1.020, and later on in the month it had on one occasion dropped to 1.008, the lowest point it ever reached at any time.

On June 16, 1886, while on a driving-tour, and unable to fully carry out the details of treatment, the daily quantity of urine rose, and with it the specific gravity to 1.033, and both the oxalate and uric acid appeared abundantly in the urine. At this time, also, the pain was very widely distributed, reaching even to the bladder and testicles. The quantity of water also rose to six pints, and the specific gravity to 1.030.

When treatment was again regularly resumed, the water fell to from three to three and one-half pints, and finally, on July 31st, to forty ounces, and specific gravity to 1.026, under liberal potations of the so-called soda-spring of Great Barrington, Mass. (This water, however, is not alkaline.) But on resumption of the clysmic water, while the specific gravity remained at 1.036, the daily quantity of water fell to thirty-six ounces.

On September 13th the patient had so far improved that liberal additions were made to his diet in the way of water-melons, peaches, and pears, and the daily quantity of water was from fifty to fifty-six ounces.

On September 14th the urine was found to contain four hundred and seventy grains of urea, which is not far from the normal amount, that has been placed at five hundred grains for an adult male (Landois and Stilling).

On October 18th the patient saw a prominent surgeon of New York, at my suggestion, in consultation, and he advised the application of an issue as a counter-irritant. Accordingly a nitric acid issue was located in the axillary line just below the free border of the ribs, and it was kept open by an issue-pea until the middle of April, 1887, or about six months.

On December 15, 1886, the water fell to thirty-nine ounces and specific gravity to 1.014. In the middle of April, 1887, it was found that the former area of tenderness was much diminished, as also the dulness on percussion, and extended no farther forward than the line of the nipple and only about one inch below the free border of the ribs. Urine normal in every respect.

On April 30th Mr. S—— sailed for Europe, to make a summer tour, feeling himself a comparatively well man.

Such a case as the foregoing illustrates what has been often termed by Fagge[1] hepatic dyspepsia. In such cases he says the patient often experiences pain in the right hypochondrium, and sometimes shooting pain in the same region. Pain, also, is sometimes referred to the right, sometimes to the left shoulder; the bowels are often confined, and there is a tendency to piles. He finds that these symptoms are generally last seen about the middle period of life, and in persons who take little exercise and eat and drink to excess, but are soon reversed when the patient takes up more active out-door occupation. The period of life corresponds to the time when men have passed the most active period of their life, and are beginning to "lay off," take things more easily, and to enjoy life, as they term it. And it is good reasoning to

[1] Fagge: Practice of Medicine, ii., 263.

maintain that a certain part of the train of symptoms is due to a congested liver, although it is not this alone, as we have seen. Now, when this organ is endeavoring to excrete *urea* as a soluble substance (CH_4N_2O), it only succeeds in eliminating a rather insoluble one ($C_5H_4N_4O_3$), a less perfectly oxidized body. But after the blood has carried the non-soluble uric acid to the kidney, it may for some reason, probably owing to the deficiency of the watery elements of the urine, be deposited in a crystalline form. Thus we have gravel, or lithiasis as it is called, and stone, or calculus.

This term *lithæmia* is now used to indicate what was once known as "suppressed" or "latent" gout. Sometimes such an attack will be felt in the stomach some hours after a hearty meal; it will be spasmodic in character and of short duration; after it has passed, the patient will feel a sense of soreness or tenderness in the stomach; or the patient may have violent cramps or pain in the bowels, with hemorrhage, or a peculiar headache that comes on after some indiscretion in diet.

17 East Forty-fourth Street.

NOTE ON THE VALUE OF CALOMEL IN CERTAIN DISEASES OF CHILDREN.[1]

By GEORGE B. FOWLER, M.D.,

Professor of Clinical Medicine and Medical Chemistry, New York Post-Graduate Medical School; Visiting Physician to Bellevue Hospital and to the New York Infant Asylum.

It is not my purpose to present to you an elaborate paper embodying the details of the introduction, centuries ago, and subsequent history of calomel. These are all given in text-books, and are common property I assume that I am addressing an audience which is familiar with the extraordinary vicissitudes to which this remedy has been subjected; how it has been used and abused; how it has been vaunted as almost a universal panacea, and how it has been condemned as a dreadful curse. It has in turn been a "byword and a reproach," and an indispensable remedy.

When I began to practise medicine, seventeen years ago, calomel was experiencing one of its periodical disgraces. If you said calomel to a patient, the effect was like drawing a pistol on him; and even now there are many nervous people who dodge if they suspect you of prescribing this medicine.

I will admit that calomel has been employed very carelessly, and has caused a great deal of discomfort and harm. Yet it has always possessed a peculiar interest for me. I am accustomed to regard it as one of the few green hills on the otherwise pretty level and barren plain of therapeutic experience. It is an unpleasant and suggestive commentary upon the practice of medicine that there should be so much variation among us in our estimation of the value of remedies, and that the specific of to-day should so often be the worthless and forgotten drug of to-morrow.

This state of things is accounted for by our ignorance of the nature of disease. The more obscure the disease the greater the number of remedies advised for its treatment, and, as the vast majority of our ills have hitherto been beyond our comprehension, pharmaceutical chemists have been stimulated to flood us with new substances and new forms of old ones, and the result is we have an enormous materia medica, a great part of which is worthless, and a great deal of which most of us know very little about. After one has been in practice for ten years he begins to gather to himself a few medicines upon which he generally relies. While he is not indifferent to the novelties of the pharmacist, he is not eager to adopt them; and the glowing accounts of their unfailing virtues may attract, but they do not capture him. He believes in the "survival of the fittest," and awaits the verdict of time. I contend that such a disposition and course are safe and sound. The time to try a new remedy is when the older ones fail, otherwise we would be very unstable indeed. Alas, we are unstable, because we do not pay enough attention to the action of remedies. Now, if any medicine has "survived" it is calomel, and it must therefore be "fit."

According to my experience calomel is a very valuable agent in the treatment of some diseases, of which I can with propriety speak before this special Society, namely, certain affections common to children.

Diarrhœas.—Diarrhœas in children are of varied severity, and may depend, in otherwise healthy individuals, upon several different causes: over-feeding, improper feeding, dentition and other nervous influences, atmospheric disturbances, and changes of temperature. Whatever the cause, the first thing to happen is an arrest of, or interference with, digestion. The food then begins to act as a mechanical irritant, or, ptomaines and poisonous gases being produced, as a chemical one, and diarrhœa ensues. Here calomel, given in one-sixth-grain doses, and combined with the bicarbonate of soda and a little sugar, repeated every half-hour, until one-half or one grain, according to the age of the child, has been administered, will, in most cases, relieve the symptoms. Of course the diet must be carefully regulated, and it may be necessary, after the bowels have moved several times as an effect of the medicine, to administer small doses of Dover's powder at intervals of two or three hours—one-fifth to one-half grain.

My belief is that the remedy acts here as a cathartic and as an antiseptic. It also relieves the congested mucous membrane, which condition is bound to exist when the disturbance has lasted for any time. If there is vomiting, I know of no medicine which has more effect in quieting that symptom. I proceed in the same manner in *entero-colitis*, and in all other forms of the ordinary diarrhœas of children. In cholera infantum I have seen excellent results, but here I resort heroically also to stimulants, and the cold or hot water enemas, as the case requires.

In all the common *derangements of digestion* where slight diarrhœa may or may not alternate with constipation, and hard balls of pale fæces are voided, I give calomel in minute doses twice a week until the bowels are uniformly loose. Then I gradually reduce the frequency of the dose, and finally, after about three weeks, stop it altogether. For peevishness, fretfulness, anorexia, accompained or not with slight fever, calomel is the remedy.

For *intestinal worms* I use nothing but this agent. In fact, whenever I desire a cathartic effect I rarely employ any other medicine than this salt of mercury.

It has long been known that calomel caused an increase of the discharge of urine, and within a year or two several papers have appeared reviving the treatment and attempting to explain its action in this connection. I have employed it in two cases of *pleurisy* with the best results. The urine in both instances was markedly increased, and this, together with the slight catharsis, was effective in rapidly causing absorption of the fluid. It is certainly indicated in other dropsical conditions. I deem it safer and more active than digitalis and acetate of potash, to say nothing of its preference as regards taste and ease of administration. In *pneumonias* of children, where there is danger from œdema of the lung, or suffocation from accumulated mucus, I have seen calomel demonstrate its diuretic and absorbent powers by relieving these conditions and averting the danger.
